A supplementary indication for the administration of thiamine hydrochloride occurs in patients with ethylene glycol poisoning. As shown in [Fig. 109–2](#), a minor pathway for the elimination of glyoxylic acid involves its conversion to α -hydroxy- β -ketoadipate by α -ketoglutarate: glyoxylate carboligase, a thiamine and magnesium-requiring enzyme. There are no data to support an increase in α -hydroxy- β -ketoadipate formation following thiamine administration in ethylene glycol-poisoned animals or humans. However, animal models of primary hyperoxaluria show increases in urinary oxalate during thiamine deficiency, suggesting at least a potential importance of this pathway.^{42,113} Because therapy is benign and inexpensive, it is prudent to administer standard doses of thiamine to patients with suspected or confirmed ethylene glycol poisoning.

Standard doses of thiamine should also be given to patients with alcoholic ketoacidosis (AKA). Glucose is required to stimulate insulin secretion, which subsequently terminates ketogenesis. Since by definition AKA occurs in malnourished alcoholics who are at risk for Wernicke encephalopathy, parenteral thiamine administration seems justified ([Chap. 80](#)).⁸

Routine thiamine administration should also be considered in patients with congestive heart failure and long-term use of diuretics. Diuretics enhance renal thiamine elimination.⁹⁸ In one randomized trial, 200 mg of daily intravenous thiamine was able to increase cardiac ejection fraction by 22% at 7 weeks.¹⁰¹ A more recent study showed that a daily oral dose of 300 mg of thiamine in patients with chronic heart failure was able to increase left ventricular ejection fraction by 10% over placebo.⁹⁴

ADVERSE EFFECTS

Very few complications are associated with the parenteral administration of thiamine. The older literature emphasized intramuscular administration because of numerous reports of anaphylactoid reactions associated with intravenous thiamine delivery.^{30,85,93,107,130} It is generally believed that these reactions resulted from responses to contaminants rather than thiamine itself. Despite the availability of purer, aqueous preparations of thiamine, rare adverse reports still occur.^{6,72,83,106} Although the intramuscular route is theoretically comparably efficacious in a healthy individual, many patients requiring thiamine may have diminished muscle mass or a coagulopathy, exacerbating the potential for pain and unpredictable absorption. The safety of thiamine use was evaluated in a large case series in which nearly 1000 patients received parenteral doses of up to 500 mg of thiamine without significant complications.¹³³ This study suggests that if anaphylaxis to thiamine exists, its occurrence is exceedingly rare, permitting the safe intravenous administration of thiamine to most patients.

PREGNANCY AND LACTATION

Thiamine hydrochloride is listed in pregnancy category A and is also considered safe for use in lactating mothers.

DOSING AND ADMINISTRATION

For prevention of Wernicke encephalopathy, initial therapy usually consists of the immediate parenteral administration of 100 mg of thiamine hydrochloride. This can be given either intramuscularly or intravenously, but the oral route should be

avoided because of its unpredictable absorption. In countries where thiamine propyl disulfide (a lipid soluble thiamine preparation) is available, the oral route may be considered equally efficacious for the replacement of serious thiamine deficiencies.^{7,119} Although there are no dose finding studies, some authorities recommend daily doses as high as 250 mg/d in high-risk patients without signs and symptoms of Wernicke encephalopathy.¹¹⁸ Current recommendations also exist for patients on total parenteral nutrition (3–3.5 mg/d), enteral feeding (2.2–2.9 mg/1500 kcal), and renal replacement therapy (100 mg/d).¹⁰⁵

The practice of requiring the administration of parenteral thiamine prior to hypertonic dextrose in patients with altered consciousness is illogical.⁴¹ Besides the fact that the first dose of dextrose is unlikely to cause thiamine deficiency, thiamine uptake into cells and activation of enzyme systems is slower than that of glucose uptake, which suggests that even pretreatment with thiamine offers little benefit over posttreatment.¹¹⁴ Despite these limitations, it is prudent to administer 100 mg of parenteral thiamine at the time of initial dextrose administration. The biochemical link between dextrose and thiamine is obvious, which demonstrates to the clinician the scientific basis for the administration of thiamine. Although thiamine is unlikely to offer immediate benefits for patients with altered consciousness, it will offer some long term protection for these individuals at risk and initiate therapy for a serious, insidious, and easily overlooked disorder.

For treatment of Wernicke encephalopathy, in some patients, symptoms such as ophthalmoplegia are reported to respond rapidly to as little as 2 mg of thiamine; however, the other neurologic and cardiovascular manifestations of thiamine deprivation may necessitate higher doses and may respond more slowly, if at all. Although many sources recommend that daily doses of 100 mg of thiamine are sufficient as in preventive therapy, others recommend initial doses as high as 200 or 250 mg,^{2,121} based on limited data. It is noteworthy that current guidelines recommended by the British National Formulary and the Royal College of Physicians, British Association for Psychopharmacology, the European Federation of Neurological Societies (EFNS), and the National Institute for Health and Clinical Excellence (NICE) guidelines all suggest that the initial thiamine regimen for patients with Wernicke encephalopathy is 500 mg intravenously three times daily for 2 to 3 days and 250 mg intravenously daily for the next 3 to 5 days.^{36,67} This increase over formerly recommended regimens is reflective of reports of patients' failing standard therapy and the safety of parenteral thiamine.

Because of the safety of thiamine hydrochloride, and the urgency to correct the manifestations of thiamine deficiency, up to 1000 mg of thiamine hydrochloride can be used in the first 12 hours if a patient demonstrates persistent neurologic abnormalities.⁷⁵

For ethylene glycol poisoning and AKA, 100 mg intravenously is recommended.

FORMULATION AND ACQUISITION

Multiple manufacturers formulate thiamine hydrochloride for intravenous or intramuscular administration. Typical concentrations are either 50 or 100 mg/mL. Although more concentrated solutions are available, their use is usually reserved for preparation of total parenteral nutrition solutions. Thiamine available in the United States is formulated in 0.5% (5 mg/mL) chlorobutanol. In the United Kingdom (UK), the formulation Pabrinex is chlorobutanol free. Chlorobutanol is a sedative with a long elimination half-life, but doses of 600 mg were given to human volunteers without complication.¹²² Thus UK and EFNS recommendations of 1500 mg/day of thiamine would only deliver 75 to 150 mg of chlorobutanol depending on which preparation was used. Even with the long elimination half-life, many days of high dose thiamine could be administered without delivering a single sedating dose.

SUMMARY

- Thiamine is an essential vitamin for cellular energy.
- Thiamine deficiency presents as either Wernicke encephalopathy or beriberi.
- Wernicke encephalopathy manifests as ataxia, ophthalmoplegia, altered mental status, decreased deep tendon reflexes, metabolic acidosis with elevated lactate, and hypothermia.
- Parenteral administration of 100 mg of thiamine will likely protect an individual for 1 to 2 weeks. When Wernicke encephalopathy is present or suspected, higher doses of thiamine are needed.
- Although thiamine requirements are based on caloric intake, there is no evidence that thiamine must be given prior to dextrose administration.

SC7 SPECIAL CONSIDERATIONS

Assessment of Ethanol Induced Impairment

Robert B. Palmer

INTRODUCTION

Myriad medical texts describe the medical consequences of acute and chronic ethanol use. The purpose of this discussion is to describe the history and use of assessments of ethanol induced impairment, primarily in a legal context. Some of the principles described may, however, be extrapolated from the legal to the medical setting. Throughout this chapter, the terms ethanol and alcohol are used interchangeably to retain the forensic, legislative, and medical contexts in which the terms are utilized.

HISTORY

Numerous well designed laboratory studies assessing alcohol induced impairment have been published. However, application of study results to actual cases of possible driving impairment or over service of alcohol in a drinking establishment may be inaccurate without an understanding of the origin of laws governing these activities. Although the intoxicating effects of ethanol have been known for centuries, the advent of mechanized transportation spawned increased public and legal scrutiny. Concern was expressed over the potential adverse safety implications of driving while intoxicated, not just for the impaired driver, but also for other persons (passengers, other drivers, pedestrians) and property. Although railroads had regulations against the operation of equipment while intoxicated dating back to the 19th century, the first arrest for drunk driving in an automobile was that of a London taxicab driver in 1897.²⁰ The realization that alcohol intoxicated motor vehicle operators were a public health issue worthy of legal scrutiny soon followed, and legislation was enacted to combat “drunken driving,” with New York being the first US state to enact such a law in 1910.²⁰

In early laws, “drunken driving” was poorly defined and relied heavily on observable signs of gross intoxication. Attempts at legislative clarification of language resulted in terms that were nearly as nebulous, such as “alcohol impaired” and “under the influence.” Prior to the landmark works in Sweden by Widmark and in the United States by Heise, evaluations of driver impairment were predominantly based on the “expert” testimony of an evaluating physician and the arresting police officer, as well as behaviors reported by witnesses. These evaluations were observational rather than scientifically based, and such nonsystematic and nonobjective testimony was often dubious and frequently plagued by exaggeration of behaviors (eg, staggering gait, incoherent speech).

The development of analytical technology capable of measuring the concentration of alcohol in blood gave rise to the idea that diagnosis of intoxication might be assisted by an objective chemical test result. The theory behind this idea being simply, the higher the blood alcohol concentration (BAC), the more drinks the individual must have consumed and therefore, the greater the degree of impairment. It was, therefore, reasoned that there may also exist a legally punishable limit of alcohol in blood or other biological matrix. Although the assignment of a specific clinical effect to a given BAC is not rigorously applicable to evaluation of an individual case, the general trends when examined across a population formed the foundation of many modern driving while intoxicated (DWI) laws.

Despite centuries’ worth of knowledge of the effects of alcohol and decades of efforts to articulate drunk driving standards, a single universal definition of “alcohol intoxicated” still does not exist. A typical medical definition may focus on altered mental status, ataxia, or the ability to care for oneself, whereas the focus of a legal definition may be on the ability to safely operate a motor vehicle or whether the patron of a bar or restaurant should be served additional alcohol. A lay public definition may include parts of both.

Although alcohol intoxication may be an important factor in a nearly infinite number of settings, two of the most common legal circumstances involving toxicology consultation for alcohol-related issues are (a) alcohol impaired operation of a motor vehicle and (b) so-called “dram-shop” cases when an already intoxicated individual is served alcohol. Discussion of alcohol use in the workplace and abstinence monitoring are beyond the scope of this discussion.

PER SE LIMITS

With the advent of analytical measurements capable of quantitatively determining BAC and the increasing public awareness

of the dangers associated with drinking and driving, legislation based on BAC began to appear. Although the initial laws did not define the specific BAC that established illegality in the operation of a motor vehicle, they did allow for the use of BAC results as supportive evidence of intoxication. The first states to incorporate BAC into drunk-driving statutes were Indiana and Maine, which did so in 1939.²⁷ The approach taken by the Indiana legislature resulted in a three-tiered statute, which stated that a BAC of less than 50 mg/dL was considered presumptive evidence of no intoxication, a BAC between 50 and 100 mg/dL was considered supportive evidence of intoxicated driving, and a BAC of greater than 150 mg/dL was considered *prima facie* (ie, obvious and evident without proof) evidence of guilt. From a legal perspective, *prima facie* evidence shifts the burden of proof from the accuser having to substantiate the charge to the defense to rebut the allegation. It is this legal perspective from which the so-called “per se” standards are derived—that is, an individual whose BAC exceeds a predetermined concentration is guilty “per se” of driving while impaired by alcohol, even without any other evidence of intoxication or impairment.

Early drunk-driving standards established in the Uniform Vehicle Code made reference to a BAC at which there was “no doubt of obvious intoxication”; this BAC was defined as 150 mg/dL. However, by 1960, as data regarding alcohol related motor vehicle crashes became available, most (but not all) states adopted a more rigorous per se BAC driving standard of 100 mg/dL.²⁷ This reduction in the per se legal BAC for a DWI charge was supported by powerful medical and political groups, including the American Medical Association (AMA). Interestingly, the AMA recommendation also noted that some persons were “under the influence” or impaired in their ability to safely operate a motor vehicle at BACs of 50 to 100 mg/dL. Despite newer drinking and driving laws defined on the basis of an objective chemical test, many state laws still contained older vague language such as “intoxicated,” “visibly intoxicated,” and “obviously intoxicated,” which forced legislators to define more clearly and objectively.

In 2000, the National Highway Traffic Safety Administration (NHTSA) reported that of 41,471 motor vehicle fatalities, 38.4% were alcohol related; this corresponded to an average of one alcohol-related traffic fatality every 31 minutes.⁵⁴ Although the NHTSA statistical methods likely overestimated the number of actual fatalities involved in alcohol-related crashes, there is little argument that alcohol use increases crash risk. Epidemiological assessments demonstrate that the probability of causing an alcohol-related motor vehicle crash increases slightly at a breath alcohol concentration (BrAC) of 50 mg/dL. The risk of causing a crash is increased by roughly four-fold at a BrAC of 80 mg/dL, seven-fold at a BrAC of 100 mg/dL, and 25-fold at a BrAC of 150 mg/dL.^{4,27} In 1994, a successful campaign vigorously supported by the AMA and Mothers Against Drunk Driving (MADD) encouraged all the states in the United States to lower the BAC used to define per se intoxicated driving to 80 mg/dL.²⁰ Although all states technically have the right to set drunk-driving statutes at their discretion, the anti-drunk-driving political lobby was successful in convincing the US government to require a minimum legal drinking age of 21 years and a mandatory per se BAC statute of 80 mg/dL in order to receive federal highway funding.²⁰ Consequently, as of July 2004, all states in the United States, the District of Columbia, and Puerto Rico conform with federal recommendations defining a BAC of 80 mg/dL as a violation of motor vehicle code. Lower per se BACs are applied to interstate commercial drivers (40 mg/dL) and pilots of aircraft (40 mg/dL, with no alcohol consumed within 8 hours prior to acting as pilot in command), as well as minors (10–20 mg/dL, depending on the state and 20–50 mg/dL in some European countries). Additionally, some states in the United States, such as Colorado, have lower per se statutes for the slightly lesser charge of driving while ability impaired (DWAI), which may be invoked when a driver’s BAC is between 50 and 80 mg/dL.

Laws addressing per se driving under the influence (DUI) limits are based on ethanol concentrations measured in whole blood. BrAC limits (which are arithmetically linked to BAC) are also frequently specified in per se statutes. As such, the use of appropriately conducted breath alcohol measurements eliminates the need to collect a blood specimen from a suspect. Per se limits, as described above, apply to the ability to safely accomplish specifically defined tasks such as driving an automobile or flying an aircraft. It is, however, imperative to understand that per se BACs do not define drunkenness or alcohol intoxication in nondriving situations, and their use in circumstances not involving motor vehicle operation is generally inappropriate.

The legal significance of a per se limit is that there is no requirement for behavioral evidence of intoxication, as long as the measured BAC exceeds that established by the legislature. Since their enactment, numerous legal arguments have challenged the constitutionality of per se drunk-driving laws. Issues including a lack of due process through application of the “void for vagueness” doctrine, reliability of breath testing results, and the distinction between blood alcohol and breath alcohol have all formed bases for legal challenges to per se laws.²⁰ However, despite such challenges, the courts have consistently upheld the laws.

ANALYTICAL CONSIDERATIONS

Accurate measurement of ethanol concentration in various biological matrices can be done using a number of analytical techniques. Historically, Widmark used wet chemical oxidation, using potassium dichromate and excess sulfuric acid followed by iodometric titration of the remaining amount of oxidizing agent. Although this method is effective, it is laborious and lacks specificity if other volatiles (eg, methanol, acetone, ether) are present, because they are also oxidized,

giving a falsely elevated ethanol result. Such wet chemical methods are obsolete and no longer used in forensic and clinical laboratories.

Enzymatic ethanol assays based on alcohol dehydrogenase (ADH) are commonly used, especially in high-throughput laboratories. The oxidation conditions of enzymatic methods are milder than wet chemical methods, and acetone, which was the most troublesome interference with wet chemical methods, is not oxidized by ADH. Interferences by other aliphatic low-molecular-weight alcohols such as methanol and isopropanol are known to occur with ADH isolated from humans and other animals; this interference is reduced by using yeast-derived ADH, which shows greater selectivity for ethanol.^{28,51} Specific enzymatic methods used for ethanol analysis in body fluids include enzyme multiplied immunoassay technique (EMIT), fluorescence polarization immunoassay (FPIA), and radiative energy attenuation (REA), which is related to FPIA (Chap. 6). Comparative study of ethanol determination by REA and gas chromatography shows excellent agreement in precision and accuracy between the two techniques.¹¹ Both high serum lactate and elevated lactate dehydrogenase concentrations interfere with ADH based methods of ethanol analysis, including providing false positive results in serum specimens from alcohol-free patients.^{2,36}

The greater selectivity for ethanol of gas chromatographic (GC) methods make this technique the mainstay for quantitative analysis in most forensic laboratories. Typically, the GC method involves head space sampling (HS-GC), which capitalizes on the volatility of ethanol, eliminates some potential interferences, and shortens run time. Samples to be run by HS-GC are first diluted (typically 1:5 or 1:10) with an aqueous solution of internal standard. This mixture is then sealed in a crimp-top vial with a rubber septum and gently heated to 122° to 140°F (50°–60°C) for 30 to 60 minutes in order to achieve equilibrium of volatiles between the gas and liquid phases. The vapor is then sampled with a syringe by puncturing the rubber septum and the withdrawn vapor injected into the instrument. Heating the sample for too long at a high temperature can result in oxidation from oxyhemoglobin.⁴³ This problem may be solved by the addition of sodium azide or sodium dithionite to block the oxidation or simply reducing the equilibrium temperature to 104° to 122°F (40–50°C).⁴³ Once chromatographic separation is achieved, various detection methods, including flame ionization (FID), electron capture (EC), and electrochemical sensing may be used (Chap. 6). Dual detection (eg, FID and EC) can also be useful in circumstances where a larger number of volatiles may need to be screened.⁴⁴

As ethanol distributes based on total body water, the water content of the matrix will affect the amount of ethanol present in a given volume or mass of biological sample. A common circumstance in which this is observed is in the difference between a whole blood ethanol determination and a plasma or serum ethanol determination. The water content of serum and plasma is 10% to 12% higher than whole blood, meaning that serum or plasma ethanol concentrations will be correspondingly higher than whole blood concentrations. Clinical laboratories most often use serum and plasma for analysis, whereas per se DUI statutes are written in terms of whole blood. Therefore, if a comparison is to be made between a serum or plasma analytical result and a legal standard, the result must be converted to an approximated whole blood ethanol concentration. Experimentally determined serum-to-whole blood ethanol ratios range from 1.12 to 1.17, whereas plasma-to-whole blood ethanol ratios range from 1.10 to 1.35.³⁷ Typically, a ratio of 1.16 is used for this conversion, and no significant difference appears to exist between the serum-to-whole blood and plasma-to-whole blood ratios.⁵⁴ Ratios between whole blood and other biological matrices such as urine, saliva, cerebrospinal fluid, vitreous humor, brain, liver, kidney, and bone marrow are published, and a table listing these ratios and the sources from which they are derived is available.¹⁰

Breath testing is commonly performed to assess BAC because of its relative simplicity and lack of invasiveness in its collection when compared with urine or blood. The analytical basis for sampling exhaled breath is that, at equilibrium, alcohol in expired air is present at a predictable ratio with blood. The gas exchange process in the lungs is complex, with significant theoretical variability.³⁴ In the United States, a blood-to-breath alcohol ratio of 2100:1 is commonly used in calibration of breath alcohol testing devices, although experimental evidence suggests that the ratio is actually closer to 2300:1.¹⁵ As such, a systematic underestimation of BAC is expected when breath alcohol results are converted to blood alcohol results. Several studies have documented this underestimation with data from suspected impaired drivers and evidential breath alcohol testing instruments.^{18,23} In 1983, Britain adopted a legal limit in breath of 35 µg/100 mL, which corresponds to a blood alcohol of 80 mg/dL, using a 2300:1 blood-to-breath ratio.²⁷ Legal statutes that include in their offense definition breath alcohol results expressed in units of g/210 L of exhaled air eliminate the need to convert breath alcohol to blood alcohol, largely mitigating arguments based on the breath-to-blood ratio.

BREATH TESTING DEVICES

Three general analytical detection principles have been extensively validated and are currently used in breath alcohol testing instruments. These are, infrared spectroscopy, electrochemical oxidation/fuel cell, and chemical oxidation/photometry.²⁴ Additionally, combination of multiple technologies is sometimes used, as in infrared/fuel cell dual detectors. Breath testing instruments may be generally divided into four broad categories: passive alcohol sensors (PASs), screening devices (preliminary breath testers, {PBTs}), breath alcohol ignition interlock devices (BAIIDs), and evidential

breath testers (EBTs).²⁴

A PAS device may be concealed in a device such as a modified police flashlight and is used to detect alcohol on or in the immediate vicinity of a subject through passive means (ie, with no requirement for subject cooperation). BAIDs are used to prevent drinking and driving by requiring the driver to blow into a sensor in order to start the ignition of the vehicle. The devices are typically installed on a court order designed to modify drinking and driving behavior in habitual DUI offenders, with the cost of installation typically borne by the offender. A number of mechanisms are employed to prevent substitution of breath samples, including preset patterns of exhalation or humming while blowing into the sampling tube. Additionally, random rolling retests may be required, failure of which may result in the vehicle's lights flashing or horn blowing. Neither PAS nor BAID results are useful for quantitative measurement of breath or blood alcohol for prosecution of a per se DUI case.

The PBT and EBT devices are the most common breath alcohol testing devices encountered in cases of DUI arrest. In this setting, PBT results are used in conjunction with observation and field sobriety tests to establish probable cause for DUI arrest. Although a measured BrAC is often provided as a digital readout on a PBT, these results are not admissible as evidence for proceedings other than probable cause hearings in most jurisdictions. Use of PBT devices is also common in nonlegal settings such as hospital emergency departments, alcohol detoxification units, homeless shelters, and workplaces. As with DUI prosecution, these results are generally used for screening for alcohol presence and not for establishing impairment.

In contrast to PBT results, measurements from an EBT device are admissible in court and administrative proceedings and can be used as the basis for establishment of per se DUI cases without the necessity of blood collection and analysis. Although mobile EBT devices are available, most often the EBT is maintained in a fixed location such as a police station. For the results to be considered valid and admissible, the operator of the EBT must be trained and certified, and the operation must be performed using an accepted testing protocol.

Required procedures for the use of EBT devices exist for the both the subject as well as the instrument. The subject must have a period of alcohol deprivation of at least 15 minutes in which trained personnel observe him or her for a minimum of 15 minutes to ensure not only that no additional ethanol is consumed, but also that no regurgitation, emesis, or eructation occurs, which could result in residual ethanol in the mouth prior to breath alcohol analysis. With respect to the instrument, both blank and control analyses must be performed prior to analysis of the subject sample. A blank analysis, typically done with room air, purges the instrument of contamination from previous samples and demonstrates a lack of environmental contamination. A control analysis is performed on a gaseous ethanol sample of known concentration, usually an ethanol gas canister or wet bath simulator, and demonstrates proper instrument calibration and maintenance. Certification of instrument maintenance of calibration must be documented, demonstrating compliance with applicable rules, regulations, laws, and standards for routine maintenance, troubleshooting, and corrective actions. These documents are then retained for a relevant time period after inspections are complete. Additional documentation for individual cases should include written verification that all steps in the accepted protocol were followed. This documentation may also include automated printouts from the analyzer used, and well as copies of manual checklists.²⁴

Beyond the required procedures, additional recommendations include the use of g/210 L as the reporting units, rather than reporting breath alcohol concentration as a converted blood alcohol concentration of %w/v, g/100 mL, or g/dL. Serial collection and analysis of at least two separate sequential breath samples taken 2 to 10 minutes apart should be done in order to demonstrate the absence of residual mouth alcohol, instrument artifacts, frequency interference, and spurious results. Agreement of the serial results must be within prescribed limits (usually, 0.02 g/210 L) to be considered acceptable.²⁴

STANDARDIZED FIELD SOBRIETY TESTS

A driver whose BAC exceeds the established legal standard is considered per se intoxicated and may be convicted without behavioral evidence of intoxication. However, some objective findings of impairment may be important in establishing probable cause to demand chemical testing, initiate a DUI arrest, or prosecute a charge of impairment, without invoking per se limits. In these settings, results of a specific group of behavioral tests may be of value in discriminating and prosecuting an impaired driving charge, although submitting to these behavioral tests is typically voluntary. Additionally, an objective measurement of alcohol effect may be helpful in assessing alcohol-related impairment in nondriving situations, where it is inappropriate to apply per se standards.

Under a contract with the NHTSA, a group of 15 candidate sobriety tests were evaluated in a laboratory study.⁹ From this original group, the investigators developed a series of three specific tests that have subsequently been standardized as a test battery, known as standardized "field sobriety tests" (FSTs), for assessing driver impairment in the United States. The three tests comprising the standardized FSTs are the one-leg stand (OLS), walk-and-turn (WAT), and horizontal gaze nystagmus (HGN). Descriptions of these tests are provided in [Table SC6-1](#).

TABLE SC6-1. Standardized Field Sobriety Tests³⁹

Test	Test Description	Test Scoring ("clues")
One-leg stand (OLS)	With the arms at sides, raise one foot at least 6 inches off the ground and stand on the other foot for at least 30 seconds.	4-point scale 1. Putting foot down 2. Hopping 3. Swaying 4. Raising arms Any two "clues" is failure.
Walk-and-turn (WAT)	Balance with feet heel-to-toe and listen to test instructions. Walk nine steps heel-to-toe in a straight line, turn 180 degrees, and walk nine more steps heel-to-toe, while counting steps, watching feet, and keeping hands at sides	8-point scale 1. Inability to maintain balance in the starting position 2. Starting too soon (eg, prior to completion of instructions) 3. Stepping off the line 4. Not touching toe to heel 5. Raising arms 6. Improper turn 7. Stopping 8. Wrong number of steps Any two "clues" is failure.
Horizontal gaze nystagmus (HGN)	Angle of onset of nystagmus is determined for each eye.	6-point scale (three points for each eye) 1. Lack of smooth pursuit 2. Distinct nystagmus at maximum deviation 3. Onset of nystagmus before 45 degrees Cutoff is 4 "clues."

Adapted with permission from Rubenzer SJ. The standardized field sobriety tests: a review of scientific and legal issues. *Law Hum Behav.* 2008;Aug;32(4):293–313.

A 1981 study of 297 drinking volunteers with BACs ranging from 0 to 180 mg/dL who were evaluated by trained police officers showed adequate interrater reliability (correlations, 0.6–0.8) and test-retest correlations (0.40–0.75).⁴⁶ Using all three field sobriety tests, the officers were able to distinguish whether BAC was above or below 100 mg/dL in 81% of participants. Test results were observed to correlate with BAC. However, the specificity and sensitivity of each individual test was not evaluated.

In the few studies evaluating the performance of individual FSTs, correlation between test performance and BAC is generally observed. Although the correlation magnitudes for the WAT and OLS tests are low, the HGN test showed excellent sensitivity and specificity across a range of BACs.³⁸ When the BAC was 0, using the WAT test, approximately 50% of the participants were judged to be impaired, and in the OLS test, 30% of the participants were rated as impaired. When the BAC was >150 mg/dL, sensitivity in the WAT and OLS tests improved to 78% and 88%, respectively. The rate of false positives (specificity; ie, those with a zero BAC who failed the HGN test) was only 3%. As seen with the other FSTs, the sensitivity of the HGN test increased with increasing BAC, being 81% for those with a BAC between 100 and 149 mg/dL and 100% for those with a BAC >150 mg/dL. The presence of horizontal gaze nystagmus, even in alcohol-tolerant drinkers, may give this test an advantage over the WAT and OLS tests in detecting the presence of alcohol.⁸ It is noteworthy that balance and coordination can be affected by factors unrelated to alcohol consumption, such as physical disability, age, and nervousness about potential arrest; however, chronic drinkers with substantial alcohol tolerance may be able to complete balance tests with few errors, even with moderate to high BACs.⁸

The three tests utilized for field sobriety assessment have some advantages, in that they are standardized and are easily understood by test takers; in addition, personnel administering the tests can be trained in a reasonable period of time.³³ However, because the test results are approximately correlated with BAC, their use is limited by the threshold BAC they are supposed to detect. Predictably, various scientific and legal challenges to the use of the FSTs have also been made. For example, the tests were designed and validated at a time when the per se DUI limit in most of the United States was 100 mg/dL; however, that threshold is now 80 mg/dL in every state (and 20–50 mg/dL in many European countries).³³ Due to the variability of psychomotor effects of alcohol as a result of individual tolerance, FST assessments are generally not

allowed as a means of estimating BAC in court proceedings. The effects of fear, fatigue, rehearsal of test performance, the arresting officer's knowledge of estimated BAC prior to administering the standardized FSTs, and various medical conditions have not been fully addressed. It has further been argued that the studies most strongly supporting use of standardized FSTs are those conducted by NHTSA-affiliated investigators and published in non-peer-reviewed government publications. So contentious has the debate been that in 2004 Booker openly leveled the charge that, "the United States Department of Transportation indulged in deliberate fraud in order to mislead the law enforcement and legal communities into believing the test (HGN) was scientifically meritorious and overvaluing its worth in the context of criminal evidence." A comprehensive review detailing this, and other, legal and scientific issues surrounding standardized FSTs was published by in 2008.³⁹

ESTIMATING THE AMOUNT OF ALCOHOL INGESTED

The kinetic profile of ethanol in the blood has been extensively studied. In general, it is known that when blood ethanol concentration is greater than 20 mg/dL, it follows a zero-order elimination profile and then converts to first-order elimination when the concentration drops below this threshold.²⁵ In the zero-order portion of the curve, typical elimination rates range from 10 to 20 mg/dL/h in social drinkers. In one study of adult patients in an urban hospital emergency department, nonchronic users of alcohol (n = 9) demonstrated a mean elimination rate of 18.7 mg/dL/h (range, 16.1–21.4), while chronic users (n = 15; defined as more than two drinks per day, history of delirium tremens, or prior detoxification) had a mean elimination rate of 20.3 mg/dL/h (range, 16.1–24.6).⁵ The difference in elimination rates between the populations was statistically significant. Other studies have reported elimination rates of 30 to 50 mg/dL/h in chronic alcoholics due, at least in part, to enzyme induction.^{5,6} Pharmacokinetic calculations in healthy nonalcoholic persons often employ a range of elimination rates of 10 to 20 mg/dL/h in order to best bracket individual differences.⁶

The estimation of the number of drinks ingested in order to achieve a given BAC has been extensively studied and is predicated on knowing several case-specific pieces of information. First, the specific definition of a "drink" in terms of alcohol content must be stated. According to the US Department of Agriculture, a standard drink consists of 12 ounces of beer (5% v/v), 5 ounces of wine (12% v/v), or 1.5 ounces of 80 proof spirits (40% v/v); each of these drinks contains approximately 14 g of ethanol.^{6,50} The time period over which the ingestion occurred, the time of the last drink, and time of blood alcohol specimen collection must be known. It is helpful to know whether the subject was fasting or had a full stomach at the time of drinking because the presence of food in the stomach alters ethanol absorption.^{29,52} Finally, the gender, age, height, and weight of the individual should be known and considered.

Using this information, estimation of the number of drinks is possible. The original work in which the prediction of ethanol concentrations from known doses was performed by Widmark in 1932 using 20 volunteer healthy moderate drinkers (10 of each gender). This research was translated from the original German into English by Baselt in 1981.^{6,25} The basis of Widmark's work was that the BAC in the body was directly proportional to the administered amount of alcohol ("dose"); the body weight of the subject; and a unitless scaling factor that Widmark referred to as "p" rho, which corrected the subject's body weight for water content. Of note, in present-day pharmacokinetics, Widmark's ρ represents the volume of distribution of ethanol. Due to the differences in body water content between sexes, ρ was determined to be approximately 0.6 in women and 0.7 in men. The original Widmark equation is therefore written as

$$A = C \times \rho \times p$$

where A represents the total amount of ethanol equilibrated in all fluids and tissues at the time of sampling (ie, total dose ingested), C is blood ethanol concentration in g/kg, ρ is the previously described Widmark ρ factor, and p is subject body weight in kilograms. Although the calculation has served well as an estimating tool for more than 70 years, it does have some limitations, principally in the ρ factor. As a result, refinement of Widmark's original ρ was undertaken by others.^{6,53} In his work, Watson derived a method for the estimation of total body water (TBW), which takes into account not only gender but also individual age, weight, and height. Watson's method for estimation of TBW (abbreviated ΣV_d) for men aged 17 to 86 years yields the following equation:

$$\Sigma V_d = 2.44 - (0.09516 \times \text{age}) + [0.1074 \times (\text{height} \times 2.54)] \\ + [0.3362 \times (\text{weight}/2.2045)]$$

For women aged 17 to 84 years, the TBW equation is:

$$\Sigma V_d = -2.097 + [0.1069 \times (\text{height} \times 2.54)] + [0.2466 \times (\text{weight}/2.2045)]$$

In all persons, the height is measured in inches and the weight is measured in pounds. Note that the equation for men includes a mathematical term derived from age, and the equation for women does not.⁵³ The significance of this calculation is its ability to be tailored to a specific person, rather than the broad extrapolation of the relatively few subjects in the original study. Inclusion of such individual information improves the accuracy of such calculations.⁴²

The need for a more standardized approach to calculations involving alcohol in forensic medicine has been known for some time. This challenge was largely undertaken in a 2006.⁶ In this paper, the author summarizes 20 of the most common calculations with respect to alcohol. As an example, the following equation is derived to calculate the estimated dose of ethanol necessary to achieve a specific blood alcohol concentration:

$$g \text{ EtOH} = \text{BAC}_{\text{target}} + [(\beta_{1-n} \times (t_s + t_p))] \times \Sigma V_d / \text{Bl}_{\text{H}_2\text{O}}$$

where g EtOH is the ingested dose of ethanol in grams; $\text{BAC}_{\text{target}}$ is the observed blood alcohol concentration in mg/dL; β_{1-n} is a range of alcohol elimination rates (typically, 10–20 mg/dL/h); t_s is the time from the start of drinking to the last drink; t_p is the range of times from the last drink to the peak PAC (typically, 30–90 minutes); ΣV_d is the Watson TBW, which is the volume of distribution based on age, weight, height and gender; and $\text{Bl}_{\text{H}_2\text{O}}$ is the approximate percentage of water in whole blood (80.65%).⁶ Noting the inherent variability in terms such as β_{1-n} and absent specific kinetic data from the individual in question, it can be seen that results of such equations should be presented as a range, rather than a discrete calculated value.

Some legal arguments have held that ethanol is odorless. This is, however, incorrect because ethanol has a characteristic pleasant smell, with an odor threshold of approximately 50 ppm.¹³ The presence or absence of breath alcohol odor is often used by police officers in the decision to proceed further with sobriety testing. In one study, 20 experienced police officers assessed alcohol odor on 14 subjects with BACs ranging from 0 to 130 mg/dL after drinking beer, wine, bourbon, or vodka.³⁵ Assessments were initiated 30 minutes after cessation of drinking. The strength of breath alcohol odor was determined to be an unreliable indicator of BAC. Correct detection of the presence of alcohol was 85% for BACs at or above 80 mg/dL but declined with decreasing BAC or the presence of food. The authors also noted that there were only small differences in odor intensity as a function of beverage type, meaning fusel oils and other constituents of alcoholic drinks are not the primary determinant of detectable odor after absorption of the beverage.

DRAM SHOP

Liquor liability or “dram shop” laws hold the server of alcoholic beverages liable for damages or injuries caused by an individual who was provided alcohol when such service should have been refused. For example, if a minor or an individual who was already intoxicated is served alcohol and crashes his or her car, the person and/or establishment who served the alcohol may be liable for damages or injuries sustained in the crash.

Interestingly, US dram shop laws were first enacted in the mid 1800s, although they were rarely used. The initial intent of these laws was to provide financial support to the families of persons who had become “habitual drunkards” through their patronage of a drinking establishment.⁴¹ Repeal of Prohibition in the United States in 1933 shifted laws governing alcohol sales from federal to state control, resulting in state-to-state variability in alcohol availability, criminal and administrative laws, and liquor liability. There was also a move from public focus on habitual drunkenness to the damage caused by drunk drivers, as well as a paradigm shift in the standard for irresponsible service away from serving a “drunkard” to serving an individual who was “visibly intoxicated.”⁴¹ The purpose of liquor liability laws has also changed over time. In the 19th century, laws were enacted to punish tavern owners who contributed to the downfall of patrons. In contrast, current application of the laws is typically as a means to compensate innocent victims injured by an intoxicated patron. This action on behalf of the innocent victim is why liquor liability law is sometimes referred to as “third party” liability.

Beginning in the late 1970s and early 1980s, political activists began to take note of dram shop laws as an effective means for prevention of drunk driving. Outreach began to bring attention to irresponsible commercial and social service of alcohol. Various drunk-driving prevention strategies emerged, including “server intervention” (ie, the practice of bar or restaurant workers intervening to prevent an intoxicated patron from driving). Interestingly, although the goal of keeping intoxicated patrons from “getting behind the wheel” is certainly praiseworthy, these programs put notably less emphasis on preventing intoxication in the first place. The 1983 Presidential Commission on Drunk Driving recommended dram shop liability and server intervention as drunk-driving prevention strategies, and federal grant funds for state drunk-driving initiatives also listed such programs as qualifying criteria.¹⁶

Alcoholic Beverage Control agencies in the various states are responsible for reviewing and approving liquor licenses of commercial establishments, collecting taxes, and enforcing criminal and administrative laws prohibiting service to minors and intoxicated persons. Largely as a tool to improve public perception of the industry, the alcoholic beverage producers have largely been responsible for development of training programs for servers in the retail community. Numerous programs offering Responsible Beverage Service (RBS) training for servers are administered at the state or regional level, or even sponsored by the server’s employer themselves. Calls for greater organization and standardization of RBS programs in the United States have been answered, at least in part, by the Responsibility Hospitality Council, whose work has focused on developing minimum training standards for legitimate RBS training.⁴¹ Although such standards

are often welcomed by regulators, some restaurant associations and owners have expressed concern over cost and compliance standards associated with RBS mandates. Nonetheless, the legal climate seems to dictate that alcoholic beverages be served in a “responsible” manner and that liability for “overservice” falls on the serving establishment. It is also noteworthy that cases putting liability onto individuals serving alcohol socially in their home have been successfully argued.

INTOXICATION AND ESTIMATION OF BLOOD ALCOHOL CONCENTRATION

Neither the characteristic odor of ethanol nor various markers of alcohol exposure (eg, ethyl glucuronide, ethyl sulfate, carbohydrate deficient transferrin, and so on) are useful in estimating BAC or degree of intoxication. The ability of an individual to estimate his or her own BAC accurately is poor.^{30,40} A lack of accuracy in estimating BAC is also observed in trained medical providers and police officers.^{3,12} A large confounding factor in these observations is tolerance. Greater tolerance, as occurs in heavy drinkers and alcoholics, imparts greater difficulty in detecting the clinical effects associated with alcohol intoxication.

Tolerance involves a central adaptation to the intoxicating effects of alcohol. As such, persons with significant tolerance to the effects of ethanol may not manifest signs of intoxication despite having a high BAC. Multiple case reports and case series in the medical literature describe alcoholic individuals with very high BACs but muted or absent clinical effects.^{14,22,26,32,45} As a result of tolerance in the alcoholic population, it may not be possible to detect clinical intoxication even though an individual has a high BAC. This circumstance does not, however, suggest that even in the clinically sober alcoholic that driving abilities are unaffected and the individual is necessarily capable of safely operating a motor vehicle.³ Furthermore, tolerance has no bearing on the potential prosecution of a DUI case on a per se BAC basis.

The circumstance is slightly more straight forward in the social drinker. The intensity of the effects of alcohol on the central nervous system (CNS) is generally proportional to the concentration of alcohol in the blood. Dubowski has tabulated the stages and effects of acute alcohol intoxication, and these tables are used in educational programs and some legal proceedings. In general, the greater the BAC, the greater the clinical effect observed.

However, while useful as a pedagogic tool for explaining the continuum of alcohol intoxication, the table must be used with care as the effects are defined only over a population, thereby making assignment of a specific effect or degree of effect in an individual impossible. The inherent individual variability in the table is apparent in the fact that the BAC ranges for the various stages of alcoholic influence overlap. Furthermore, the population and methods used to compile the table are not described, and the table itself has not been subjected to peer review.

The CNS effects of alcohol intoxication are typically more pronounced on the ascending portion of the blood alcohol kinetic curve than on the descending side due to acute tolerance.¹⁹ In other words, the clinical effect of intoxication is greater during the absorptive arm of the kinetic curve than on the elimination arm, even though the same blood alcohol concentration is measured in both kinetic phases. This principle is known as acute tolerance, or the Mellanby effect.

In a dram shop case, the ultimate question often becomes this—what is the typical BAC at which it is more likely than not that the average nontolerant individual will exhibit signs of intoxication (eg, the odor of alcohol on the breath, clumsiness, difficulty walking or maintaining balance, slurred speech, inappropriate behavior) that are apparent to a bystander or third party? A 1986 report by the Council on Scientific Affairs of the AMA examined a review of seven studies spanning 50 years that included more than 6500 participants for identification of BACs at which individuals appeared “drunk” (ie, clinically intoxicated).¹ BACs were stratified by increments of 50 mg/dL, beginning at 0.0 to 50 mg/dL and extending to 401 mg/dL. In the lowest BAC group (0.0–50 mg/dL), observer perceptions of subject drunkenness ranged from 0% to 10%, with an average of 4%. The percentage of individuals determined by observers to be drunk increased steadily from a mean of 32% (range, 14%–68%) at a BAC of 51 to 100 mg/dL to a mean of 62% (range, 47%–93%) at a BAC of 101 to 150 mg/dL. In this latter range, four of the seven studies indicated a perception of drunkenness by less than or equal to 50% of observers. However, in the next BAC increment of 151 to 200 mg/dL, observers judged a mean of 89% (range, 83%–97%) of the drinkers to be drunk. In each of the subsequent higher increments, the mean percentage of persons classified as drunk ranged from 95% to 100% with no individual study value less than 90%. Therefore, it can be reasonably concluded that, in a nontolerant individual, a BAC of 151 to 200 mg/dL will more likely than not result in observable signs of drunkenness.

The validity of a police officer detecting intoxication in drivers involved in motor vehicle crashes also increases with increasing BAC. A 1996 report examined a total of 1336 subjects over age 15 who were admitted or died at a level 1 trauma center in Seattle during a 5 year period from 1986 to 1993 and in whom both a recorded BAC and a police assessment of sobriety were conducted.²¹ The blood alcohol measurement was conducted in the hospital, and it is not expressly stated if the analytical matrix used was whole blood, serum, or plasma. Four categories of sobriety assessment were used by police: (a) had not been drinking, (b) had been drinking—not impaired, (c) had been drinking—sobriety unknown, and (d) had been drinking—impaired. Officers used a battery of specific criteria to judge whether a driver was

intoxicated, including odor on the breath, slurred speech, chemosis, poor coordination of motor function, and the ability to simultaneously perform multiple tasks. The greatest number of drivers were in the two extreme categories: had not been drinking ($n = 746$) and had been drinking—impaired ($n = 568$). A direct correlation between measured BAC and police officer assessment of sobriety was observed. The mean BAC associated with the “had been drinking—impaired” group was 190 mg/dL with a 95% confidence interval (CI) of 180 to 200 mg/dL. Those in the “had been drinking—sobriety unknown” group had a mean BAC of 130 mg/dL (95% CI, 110–150). Among all drivers, police field assessment of sobriety had a positive predictive value of 85% with sensitivity and specificity of 91% and 90%, respectively, demonstrating recognition of drunk driving by police with a high degree of accuracy, especially in the group with the highest BAC.

Another study designed to determine the ability of police officers, who have more training than the average lay person, to make assessments about alcohol intoxication in drinking target subjects without the aid of special testing normally available to them (eg, standardized field sobriety tests or the ability to smell the odor of alcohol on the subject’s breath).⁷ This study involved 39 police officers who viewed a series of videotaped interviews with six volunteer moderate drinkers having targeted BACs in three concentration ranges: low (80–90 mg/dL), medium (110–130 mg/dL), and high (150–160 mg/dL). Based on their observations of the taped interviews, the officers answered three questions:

1. Has the persons been drinking?
2. Was it OK to serve that person one additional drink?
3. Was the person able to drive a car?

Each of the three questions could be answered “yes,” “no,” or “not sure.” A fourth question assessed the officers’ confidence in their answers as “not sure,” “little uncertain,” or “positive.” Question 2 was to be answered from the perspective of a social host or bartender, not a police officer. None of the police officers had any formal training in the management or service of alcohol to intoxicated people, such as that offered by commercial seller/server training programs such as Techniques in Alcohol Management or Training for Intervention Procedures. With respect to their answers, the police officers were fairly certain that the subjects had been drinking only in the target groups with the highest BAC (150–160 mg/dL). Officers also answered in the affirmative to question 2 (ie, that it was OK to serve the target subject another drink) the majority of the time in the low- and medium-BAC target groups but not in the high BAC target group. The percentage of officers answering affirmatively to this question was 55%, 75%, and 41% for the low, medium, and high target groups, respectively.

Multiple studies have examined the likelihood of on-premise (bars and restaurants) and off-premise (liquor stores, grocery stores, and convenience stores) as well as outdoor events like festivals to sell alcohol to obviously intoxicated persons (typically, paid professional actors pretending to be drunk).^{17,31,47–49} The results are fairly uniform in that the majority of the time the alcohol was sold or served to the individual. Additionally, it was noted that male servers/clerks who appeared younger than age 31 were more likely to make such sales and the sales were more likely to occur in off-premise establishments.¹⁷

In a typical study, the authors employed 19 actors who were specifically hired based on their ability to feign intoxication. All actors were male and ranged in age from 31 to 59 years, with a mean of 42 years.⁴⁸ The actors used a standardized script to attempt to purchase either a single vodka drink after asking what beers were available on tap (on-premise) or a six-pack of beer (off-premise). Prior to entering the establishment, the actor received specific instructions to demonstrate multiple signs of intoxication, including disheveled hair and clothing, smelling of alcohol, lack of coordination, stumbling, fumbling with money, slurring words, repeating questions, appearing forgetful, and laughing inappropriately. If the actor was asked if he was driving, he responded “no” and if he was asked if he had been drinking, he responded, “I’ve had a few beers.” Attempts at alcohol purchase were made at 223 on-premise and 132 off-premise establishments.

Of the 355 attempts, actors were able to successfully make the alcohol purchase in 280 instances (79%). On-premise establishments served the actors 76% of the time, whereas off-premise establishments allowed the sale 83% of the time. Actors and a nondrinking observer also watched for clues that the server/clerk indicated an awareness or suspicion that the buyer was obviously intoxicated. Verbal indications, including asking the buyer to leave, suggesting a nonalcoholic drink, offering to call a cab, and so on, as well as nonverbal indications, such as staring or rolling of eyes, were recorded. A similar series of observations were made of security staff, other staff/bartenders/cashiers, and other customers. In 51% of the attempted purchases, there was an indication from the server of the recognition of the intoxication of the buyer. Even within the group that recognized signs of apparent intoxication, the alcohol was sold 61% of the time. When the server made no indication of the apparent intoxication, alcohol sales were completed 97% of the time. In 45% of purchase attempts, another staff member or customer made an indication that they believed the buyer was intoxicated. Still, alcohol purchases were completed in 66% of these cases. When no other staff member or customer indicating an awareness of the buyer’s behavior, the actor was served 89% of the time. The authors concluded that sales of alcohol to obviously intoxicated individuals in some US communities is very high and recommend additional study to identify effective training and tools to mitigate such illegal sales.

SUMMARY

- Alcohol use is associated with clinical effects, which adversely affect the ability to safely operate a motor vehicle.
- Impaired driving charges may be prosecuted based on BAC and application of a per se statute, and analytical techniques capable of accurately measuring alcohol concentration in a variety of biological matrices have been available for decades.
- The ability to accurately predict a BAC after drinking is poor, not only for the drinking individual, but also for trained personnel such as police officers and medical professionals.
- Clinically apparent signs of alcohol intoxication may be difficult to detect in individuals with significant tolerance, increasing the probability of driving when BAC exceeds a per se value, or “overservice” in a bar or restaurant. Tolerance also seriously limits the applicability of tables correlating BAC with specific clinical effects in an individual case.
- While the use of standardized FSTs has become the norm in the prosecution of impaired driving cases, this battery of tests has also received significant legal and scientific criticism.

81 ETHANOL WITHDRAWAL

Jeffrey A. Gold and Lewis S. Nelson

HISTORY AND EPIDEMIOLOGY

The medical problems associated with alcoholism and alcohol withdrawal were initially described by Pliny the Elder in the first century B.C. In his work *Naturalis Historia*, the alcoholic and alcohol withdrawal were described as follows: "... drunkenness brings pallor and sagging cheeks, sore eyes, and trembling hands that spill a full cup, of which the immediate punishment is a haunted sleep and unrestful nights. ..." ⁵⁴ Initial treatments as described by Osler at the turn of the 20th century were focused on supportive care, including confinement to bed, cold baths to reduce fever, and judicious use of potassium bromide, chloral hydrate, hyoscine, and, possibly, opium. ²⁰

Some of the initial large series of alcohol related complications in the early 20th century describe alcohol use as a major public health concern. At Bellevue Hospital in New York City, there were 7000 to 10,000 admissions per year for alcohol-related problems from 1902 to 1935, with an estimated rate of 2.5 to 5 admissions per 1000 New York City residents. ³⁸ Many of these patients were described as suffering from "alcoholomania" or "acute alcoholic delirium."

A similar number of admissions to Boston City Hospital was also reported, with up to 10% of alcoholics admitted with evidence of delirium tremens (DTs). ⁵¹ The mortality at the beginning of the study among patients with DTs was 52% (1912), and DTs was the leading cause of death among admitted alcoholics. Over the ensuing 20 years, this rate declined to approximately 10% to 12%, a decrease believed to be secondary to improved supportive care and nursing.

Although alcoholics were widely recognized as having a high incidence of delirium and psychomotor agitation, whether this was caused by ethanol use, ethanol abstinence, or coexisting psychological disorders remained controversial. Isbell and colleagues, in 1955, proved that abstinence from alcohol was responsible when they subjected 9 male prisoners to chronic alcohol ingestion for a period of 6 to 12 weeks followed by 2 weeks of abstinence. ³⁶ Although they were ingesting alcohol daily, none of these prisoners developed signs and symptoms of DTs. However, during the abstinence phase, six of the nine men developed tremor, elevations in blood pressure and heart rate, diaphoresis, and varying degrees of either auditory or visual hallucinations, consistent with the diagnosis of DTs. In addition, two of the nine men developed convulsions, further linking alcohol abstinence to seizures. However, it should be noted that the high rate of development of DTs (67%) is atypical and does not represent the true prevalence found in later epidemiologic studies.

Alcoholism and the various manifestations of the alcohol withdrawal syndrome (AWS) still represent major problems in both the inpatient and outpatient setting. Ethanol is responsible for approximately 3.8% of all deaths worldwide (6.3% of men and 1.1% of women) and accounts for 4.6% of the global burden of disease (7.6% of men and 1.4% of women). ⁵⁸ The lifetime risk of alcohol use disorders in men is more than 20%, with a risk of about 15% for alcohol abuse and 10% for alcohol dependence. ⁶¹

Alcohol-related complications accounted for 21% of all medical intensive care unit (ICU) admissions, with alcohol withdrawal being the most common alcohol-related diagnosis. ⁴⁷ In other studies, 8% of all general hospital admissions, 16% of all postsurgical patients, and 31% of all trauma patients developed AWS. ²⁴ The development of AWS in postsurgical and trauma patients can increase the mortality in this population nearly threefold. ⁴

PATHOPHYSIOLOGY

Numerous studies over the past two decades provide valuable insight into the mechanism of alcohol withdrawal, allowing for better understanding of both the clinical spectrum of the disorder and potential therapeutic interventions. AWS is a neurologic disorder with a continuum of progressively worsening symptoms caused by the effects of chronic ethanol use on the central nervous system (CNS), and often exacerbated by the clinical manifestations of alcoholism (eg, nutritional depletion, impaired immunity, anemia, cirrhosis, and head trauma) (Table 81-1).

TABLE 81-1. Distinctions Among the Various Degrees of the Clinical Severity of Alcohol Withdrawal Syndrome (AWS)^a

Mild AWS

Symptoms

- Anorexia
- Anxiety
- Emotional lability
- Insomnia
- Irritability

Signs

- Diaphoresis
- Headache
- Hypertension
- Tachycardia
- Tremor (fine)

Moderate AWS (mild AWS, generally worse) plus:

- Agitation
- Tremor (coarse)

Severe AWS/Delirium Tremens (moderate AWS, generally worse) plus:

- Confusion/delirium progressing to tonic clonic seizures
- Hallucinations that may be visual, tactile, or auditory
- Hyperthermia

^aNote that alcohol withdrawal seizures and hallucinosis may occur with any degree of AWS.

The effects of chronic alcohol consumption on neurotransmitter function best explains the clinical findings. Persistent stimulation of the inhibitory γ -aminobutyric acid (GABA) receptor chloride channel complex by ethanol leads to downregulation of GABA receptor chloride channel complex.¹¹ This allows the alcohol user to maintain a relatively normal level of consciousness despite the presence of sedative concentrations of ethanol in the brain. A continued escalation of the steady-state ethanol concentration is required to achieve euphoria (ie, tolerance), which results in progressive desensitization of the GABA receptor chloride channel complex.⁴⁵ The exact mechanism by which this adaptive change occurs is incompletely understood but may involve substitution of an α_4 for an α_1 receptor subunit on the GABA_A receptor (Chaps. 14 and 15). A converse series of events occurs at the N-methyl-D-aspartate (NMDA) subtype of glutamate receptor. Binding of ethanol to the glycine binding site of this receptor inhibits the NMDA receptor function, resulting in compensatory upregulation of these excitatory receptors.³⁰ Thus withdrawal of alcohol is associated with both a decrease in GABAergic activity and an increase in glutamatergic activity. This phenomenon of a concomitant increased excitation and loss of inhibition results in the clinical manifestations of autonomic excitability and psychomotor agitation.

Repeated episodes of alcohol withdrawal may lead to permanent alterations in neurotransmitters and their receptors. In rats, repeated episodes of alcohol withdrawal leads to persistent and progressive electroencephalographic abnormalities, with further episodes of withdrawal becoming increasingly resistant to benzodiazepines. Both clinical observation and in vitro data also suggest permanent dysregulation of GABA receptors. This understanding may be an explanation for the “kindling phenomena,” which is the clinical observation of increasing severity of alcohol withdrawal among individual subjects, and the development of benzodiazepine-resistant alcohol withdrawal.⁷⁸

CLINICAL MANIFESTATIONS

Alcohol withdrawal is defined in the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-V) as the cessation of heavy or prolonged alcohol use resulting, within a period of a few hours to several days, in the development of two or more of the clinical findings listed in Table 81–1. Alcohol withdrawal syndromes can be classified both by timing (early vs. late) and severity (eg, complicated vs. uncomplicated) (Table 81–1). However, there are no adequate or fully accepted criteria by which to define these categories. Furthermore, the clinical course of AWS can vary widely among patients, and progression of individual patients through these different stages is variable.⁷⁰ In fact, some extensive alcohol users experience no withdrawal syndrome following the cessation of alcohol consumption. Recognizing these limitations, this conceptual framework still proves helpful in the clinical management of patients with alcohol withdrawal.

Early Uncomplicated Withdrawal

Alcohol withdrawal begins as early as 6 hours after the cessation of drinking. Early withdrawal is characterized by autonomic hyperactivity, including tachycardia, tremor, hypertension, and psychomotor agitation. This syndrome is sometimes called alcoholic tremulousness.⁶⁹ Although these symptoms are uncomfortable, they are not generally dangerous. Most patients who ultimately develop severe manifestations of AWS initially develop these findings, but this is not universal. At this “stage” of AWS, the symptoms are still readily amenable to treatment with ethanol, as is done daily by many heavy alcohol users.

Alcoholic Hallucinosis

Nearly 25% of patients with AWS will develop transient hallucinations, and a subset of these patients will develop alcoholic hallucinosis, a syndrome of vivid hallucinations that may last several weeks.^{26,71} Although classically these hallucinations are tactile or visual, other types of hallucinations are described. Tactile hallucinations include formication, or the sensation of ants crawling on the skin, which can result in repeated itching and excoriations. However, as opposed to what is observed with DTs, alcoholic hallucinosis is associated with a clear sensorium. The presence of alcoholic hallucinosis is neither a positive nor a negative predictor of the subsequent development of DTs.²⁷

Alcohol Withdrawal Seizures

Approximately 10% of patients with AWS develop alcohol withdrawal seizures, or “rum fits.” For many patients, a generalized alcohol withdrawal seizure may be the first manifestation of the AWS.⁶⁹ Approximately 40% of patients with alcohol withdrawal seizures have isolated seizures, and 3% develop status epilepticus.⁷⁰ Alcohol withdrawal seizures may occur in the absence of other signs of alcohol withdrawal and are characteristically brief, generalized, tonic–clonic events with a short postictal period. Rapid recovery and normal mental status belie the seriousness of an alcohol withdrawal seizure. However, for approximately one-third of patients with DTs, the sentinel event is an isolated alcohol withdrawal seizure.⁴⁹ Alcohol withdrawal seizures occurring in the presence of an elevated ethanol concentration may be a poor prognostic indicator for the development of DTs. Finally, clinicians should be cognizant that many alcoholics are prescribed anticonvulsant medications because they have a preexisting seizure disorder, often related to repetitive brain trauma.³⁵ Conversely, the use of anticonvulsants does not unequivocally indicate the presence of a preexisting seizure disorder because of the difficulty in differentiating these seizures from those of alcohol withdrawal.

Delirium Tremens

DTs is the most serious manifestation of the AWS and generally occurs between 48 and 96 hours after the cessation of drinking.⁶⁹ Many of the clinical characteristics of DTs are similar to those of uncomplicated early alcohol withdrawal, differing only in severity, and include tremors, autonomic instability (hypertension and tachycardia), and psychomotor agitation. However, unlike the other forms of AWS, DTs is associated with either (a) disturbance of consciousness (such as reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention, delirium, confusion, and frank psychosis, or (b) a change in cognition (such as memory deficit, disorientation, and language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.² Unlike the early manifestations of alcohol withdrawal, which typically last for 3 to 5 days, DT can last for up to 2 weeks (Table 81–2).

TABLE 81–2. Diagnostic Criteria for Substance Withdrawal Delirium²

- A.** Disturbance of consciousness (ie, reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
- B.** A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
- C.** The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
- D.** There is evidence from the history, physical examination, or laboratory findings that the symptoms in criteria A and B developed during, or shortly after, a withdrawal syndrome.

Note: This diagnosis should be established instead of a diagnosis of substance withdrawal only when the cognitive symptoms are in excess of those usually associated with the withdrawal syndrome and when the symptoms are sufficiently severe to warrant independent clinical attention.

RISK FACTORS FOR THE DEVELOPMENT OF ALCOHOL WITHDRAWAL

Factors determining whether an individual will develop AWS and to what severity are not well identified. The strongest predictor for the development of AWS is a history of prior episodes of AWS/DTs and/or a family history.⁴² The influence of family history on the development of AWS suggests a strong role for genetic factors. A growing number of studies have identified associated polymorphisms, including genes involved in dopaminergic neurotransmission, glutamate signaling, cannabinoid receptors, serotonin signaling, and neuropeptide Y.⁶⁸ However, these findings must be interpreted with caution. First, whether these findings represent a predisposition to greater ethanol consumption because of an enhanced mesolimbic reward system, or some other underlying pathophysiologic effect, is unclear. Second, many of the studies do not systematically divide between AWS, withdrawal seizure, and DTs, all of which may be regulated by different pathways. Finally, almost uniformly these studies are small (fewer than 200 subjects) and are racially homogenous, making it imperative that these be replicated on a larger scale and among different racial groups. Larger and more varied patient cohorts that include both women and nonwhite ethnic groups are required before any definitive conclusions can be drawn. Racial predisposition to the development or severity of AWS is not definitive, but the experience at our institution suggests that African-American patients may be at lower risk of developing severe DTs than Caucasians.¹⁴

One of the more commonly used means for accurately assessing alcohol withdrawal is the Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar) score.⁶⁶ This scoring system contains 10 clinical categories and requires less than 5 minutes to complete. However, its use is limited by the requirement of subjective assessments by the patient; they cannot be adequately performed in highly agitated or sedated patients and are difficult to use in patients with language barriers. For these reasons, we prefer the Richmond Agitation Sedation Scale (RASS), which is observer based.⁶² Scoring systems are essential not only for symptom-triggered therapy, but they also provide a basis for comparative analysis of clinical trials in ethanol withdrawal. Greater use of CIWA-Ar, RASS, or a comparable validated scale will be essential for interpretation of both genetic and treatment trials in the future.

DIAGNOSTIC TESTING

Clinical and Biochemical Predictors

Numerous attempts have been made to develop biochemical predictors for the presence and/or severity of alcohol withdrawal. Although consistent abnormalities in readily obtained laboratory values are observed in patients with AWS (eg, aminotransferases, magnesium, mean corpuscular volume), their role in predicting the severity of AWS is poorly understood. In one study, an alanine aminotransferase of greater than 50 U/L, a serum chloride less than 96 mEq/L, and a serum potassium less than 3.6 mEq/L were all associated with the development of AWS in patients admitted to a detoxification center.⁷⁵ Another noted that risk factors for DTs included a lower serum potassium, thrombocytopenia, and prevalence of structural brain lesions.²³ However, the varied and generally low specificity of these derangements makes it difficult to assess their predictive value, especially when accounting for other clinical characteristics such as prior history, initial ethanol concentration, and admission CIWA-Ar or RASS score. In addition, there is a negative association between the presence of severe alcohol withdrawal and histopathologic cirrhosis, further clouding the usefulness of routine laboratory testing for prognostication.⁵

Other investigators have focused specifically on blood ethanol concentration as a predictor for the severity of AWS in at-risk subjects. In one study of patients entering a detoxification program, an admission blood ethanol concentration of greater than 150 mg/dL had a 100% sensitivity and a 57% specificity for the need for treatment of alcohol withdrawal.⁷² At a different treatment facility, an ethanol concentration of greater than 150 mg/dL had an 81% positive predictive value for the need to use more than a single dose of chlordiazepoxide for the treatment of AWS.⁷² In addition, admission blood ethanol concentrations in patients with alcohol withdrawal seizures were twofold higher than in those without seizures, irrespective of whether or not they had a history of prior withdrawal seizures. However, these results should be interpreted with caution and in the context of the clinical presentation, as other studies yield conflicting results. In one study, an admission ethanol concentration of less than 100 mg/dL was associated with an increased risk of recurrent alcohol withdrawal seizures, and in another study, admission ethanol concentrations failed to predict the development of DTs.^{15,56} There are many potential explanations, including differences in patient population, differences in cohort size, and the late onset of DTs, at a time when ethanol concentrations would be extremely low or nonexistent.

Homocysteine and B vitamin concentrations as well as hepatic function tests are associated with the development of AWS, although there are several contradictory study results.^{32,42} Because many studies are based on small numbers of often highly selected subjects, and some are promising but not prospectively validated,⁷⁶ their generalizability is typically poor. Numerous reports document hyperhomocysteinemia in alcoholism, presumably caused by a deficiency of dietary folic acid. Furthermore, homocysteine and its metabolites can act as excitatory neurotransmitters at the NMDA receptor and cause seizures and excitatory neuronal death. In one study, serum homocysteine concentrations were predictive of alcohol withdrawal seizures.⁸ However, in this study, there was very strong correlation ($r^2 = 0.7666$; $P < 0.001$) between admission blood ethanol concentrations and homocysteine concentrations and the development of seizures, raising doubts as to whether this holds any advantage over blood ethanol concentrations.

MANAGEMENT

Alcohol Withdrawal Seizures

Alcohol withdrawal seizures are perhaps the most rigorously studied complication of alcohol withdrawal. They are generally self-limited and if treatment is needed, benzodiazepines are the preferred agents. In a randomized, placebo-controlled trial of 229 subjects with alcohol withdrawal seizures, 2 mg of intramuscular lorazepam reduced the risk of recurrent seizure from 24% to 3% ($P < 0.001$) at 6 hours, and the need for hospital admission from 42% to 29% ($P = 0.0222$).¹⁸ However, whether this interrupts the natural history of progression to DTs is not known. There is no role for phenytoin in either treatment or prevention of alcohol withdrawal seizures. In multiple trials, phenytoin was ineffective in preventing recurrent seizures.^{1,55} The most likely explanation for the failure of phenytoin is its inability to regulate GABA or NMDA receptors, the principal mediators of seizures in alcohol withdrawal. One exception to this lack of usefulness occurs in the alcoholic patient with a non-alcohol withdrawal mediated seizure, or a history of underlying seizure disorders.

Alcohol Withdrawal

In the early stages of AWS, many patients are able to self-medicate with additional ethanol consumption. Among those who seek medical attention, many patients with AWS can be safely managed as outpatients. Outpatient management has significant cost savings with little effect on treatment outcome.⁶⁴ In one study, patients who were not clinically intoxicated, had no history of either DTs or alcohol withdrawal seizures, no comorbid psychiatric or medical disorders, and a CIWA-Ar score of less than 8 were safely managed as outpatients.³ Patients not meeting these criteria were referred to inpatient detoxification centers or medical units, depending on the severity of withdrawal and other comorbid conditions.

For all patients with AWS, the initial stages of therapy remain the same and should include a thorough assessment to identify a coexisting medical, psychiatric, or toxicologic disorder. In particular, an assessment for CNS trauma and infection should include the use of computed tomography and lumbar puncture as needed. Patients with altered cognition and an elevated body temperature should receive antibiotics, pending the results of a lumbar puncture. In concert with this approach, adequate supportive care should be instituted, including maneuvers to normalize any abnormal vital signs such as hyperthermia.

Chronic ethanol consumption leads to severe vitamin and nutritional deficiencies and electrolyte disturbances that should be corrected. Specifically, thiamine should be given to all patients to prevent the development of Wernicke encephalopathy.²¹ It was historically suggested that thiamine should be given prior to the administration of dextrose to prevent precipitation of Wernicke encephalopathy.^{48,73} Although there is no evidence for this approach, the administration of thiamine (Antidotes in Depth: A24) and dextrose together is a reasonable practice. In addition, there is a high incidence of intravascular volume depletion among alcoholics, so all patients should receive adequate volume resuscitation. Of 39 deaths between 1915 and 1936 attributed to DTs in which volume status was recorded, all subjects were volume depleted.⁵¹ Finally, for patients with AWS, prevention of nosocomial complications is paramount for reducing hospital stays. Currently, in addition to adequate volume replacement, we recommend that all patients (1) be kept with the head of the bed elevated to prevent aspiration and (2) that deep vein thrombosis prophylaxis be given if the patient is bed bound for an extended period.

The association of alcohol withdrawal with severe psychomotor agitation led to early use of sedative-hypnotics. One of the first randomized trials compared chlorpromazine to paraldehyde. In both arms there was a 0% mortality, suggesting equivalency of the two treatments.²⁵ Over the ensuing years, numerous trials documented similar efficacy between paraldehyde, benzodiazepines, and antipsychotics.^{13,25,67} However, in a landmark study, 547 patients were randomized to one of four drugs (chlordiazepoxide, chlorpromazine, hydroxyzine, and thiamine) or to placebo for the treatment of alcohol withdrawal.³⁹ Patients receiving chlordiazepoxide had the lowest incidence of both alcohol withdrawal seizures and DTs, establishing benzodiazepines as a first-line agent for treatment of alcohol withdrawal. Of note, use of chlorpromazine, an antipsychotic, is associated with a significant increase in the incidence of seizures in both humans and animal models.^{10,39}

Since this study, numerous trials have compared different routes of administration among various sedative-hypnotics, both to each other and to placebo. Because of the historical use noted above, chlordiazepoxide remains widely used in outpatient clinics and inpatient detoxification services. Oral benzodiazepine administration is generally effective in patients with early or mild AWS, although initial rapid titration with an intravenous regimen may be more efficient. Benzodiazepines administered intravenously have a rapid onset of action and have displaced paraldehyde as the preferred choice for acute control. Among the benzodiazepines, diazepam offers the most rapid time to peak clinical effects, which limits oversedation that may occur following the administration of lorazepam, which has a slower onset to the peak drug effect. Because of the delayed peak clinical effect of lorazepam of approximately 10 to 20 minutes, several doses may be administered in rapid succession with little clinical effect, followed by the appearance of the sedative effect of the cumulative doses. Midazolam may be administered intramuscularly if intravenous access is not available.⁶³ Although no significant differences are observed between benzodiazepines and barbiturates in terms of mortality or the duration of

delirium, the improved pharmacokinetic profile and ease of administration favor benzodiazepines over barbiturates when an intravenous medication is required.^{3,43}

Other pharmacokinetic factors and experience confirm that diazepam is the preferred benzodiazepine for initial intravenous use in patients with moderate to severe AWS. Diazepam has a long half-life and two active metabolites (desmethyldiazepam and oxazepam). The prolonged half-life (48–72 hours) of desmethyldiazepam further extends the effective duration of action of the initial dose of diazepam.⁸¹ A retrospective review reported that the use of a single benzodiazepine rather than multiple benzodiazepines was a marker for treatment success in surgical patients experiencing alcohol withdrawal during surgical admission.⁵³ These data suggest that it is more important to sedate the patient rapidly with adequate doses of a single benzodiazepine than to use multiple agents in hopes of finding an effective regimen. Finally, it should be noted that in patients with advanced liver disease, the use of diazepam may result in a very prolonged period of sedation because of impaired clearance of the parent compound and its metabolites. Consequently, in these patients, a benzodiazepine without active metabolites, such as lorazepam, may be a better drug.

The initial management of patients with AWS should include rapid titration with a benzodiazepine to achieve sedation.⁵² An oral benzodiazepine, such as chlordiazepoxide or diazepam may be sufficient, but certain patients will require intravenous medication. The goal of therapy is to have the patient sedated but breathing spontaneously, with normal vital signs. Although normalization of vital signs is not a mandatory therapeutic endpoint, abnormal vital signs despite adequate sedation should prompt a search for comorbidities. In many patients, attaining complete sedation using a loading protocol may allow for autotitration; that is, as the AWS resolves, the blood concentrations of the benzodiazepine decrease, allowing gradual clinical recovery.⁴⁶ In practicality, most patients need periodic symptom triggered redosing with benzodiazepines to maintain adequate sedation. This is particularly important in patients with AWS and a concomitantly elevated blood alcohol concentration. Their benzodiazepine requirements using symptom triggered therapy typically matches their decrease in blood alcohol concentration.

Multiple studies suggest that if additional doses are required, they should be administered based on symptoms (“symptom triggered”), as opposed to a fixed dosing schedule.¹² In two randomized controlled trials, administration of benzodiazepine in a symptom-triggered fashion reduced both the total amount of benzodiazepine and the duration of treatment.^{19,59} In these trials, benzodiazepines were administered every hour as long as the CIWA-Ar score remained greater than 8 to 10. In both trials, symptom-triggered therapy resulted in a four- to sixfold reduction in the duration of therapy and a four- to fivefold reduction in the total amount of benzodiazepine administered, with no increase in withdrawal seizures or adverse events. Symptom-triggered doses in patients with moderate or severe AWS should be diazepam 10 to 20 mg intravenously or lorazepam 2 to 4 mg. For less symptomatic patients, oral chlordiazepoxide 50 to 100 mg should be administered. However, it is important to note that the decision to treat in the symptom-triggered group was made based on CIWA-Ar score (usually >8), which demonstrates the usefulness of standardized scoring and evaluation tools. It should also be noted that in both these trials, patients had very mild withdrawal symptoms, with mean CIWA-Ar scores of 9 to 11. While experience suggests that this same regimen is also effective in patients with more severe withdrawal and/or DTs, it has not been validated in this population. Furthermore, it must be emphasized that protocolized use of the CIWA-Ar score is dependent upon a significant history of recent heavy drinking and a communicative subject. A prospective analysis of complex medical/surgical patients enrolled in a CIWA-Ar protocol suggested that more than 50% patients failed to have recent alcohol use and could not communicate, leading to unnecessary treatment.³¹

Resistant Alcohol Withdrawal and Delirium Tremens

There is a subgroup of patients with AWS who require very large doses of diazepam or another comparable drug to achieve initial sedation.²⁹ This same group often has exceedingly high benzodiazepine requirements to maintain this degree of sedation. Subjects with resistant AWS and DTs may have benzodiazepine requirements that exceed 2600 mg of diazepam within the first 24 hours and generally require admission to an intensive care or step-down unit.^{60,79} Patients admitted to the Bellevue hospital medical ICU for resistant alcohol withdrawal had very high diazepam requirements, with a mean of 234 mg (range, 10–1490 mg) required in the first 24 hours, and individual doses of diazepam that often exceeded 100 mg, to control their agitation. At Bellevue, these patients comprise approximately 5% of all ICU admissions, with nearly 40% of patients requiring mechanical ventilation and a mean ICU length of stay of 5.7 days.²⁸

The approach to the management of resistant AWS depends on several factors, including the availability of an ICU bed. In the ICU, despite the perception of failure of high benzodiazepine requirements, we favor administration of benzodiazepines in a symptom-triggered fashion. This approach was confirmed in a study of patients who developed AWS postoperatively in the ICU.⁶⁵ In this study, a symptom-triggered strategy resulted in a shorter length of stay and a lower incidence of mechanical ventilation than did continuous infusion of midazolam. Patients who receive this therapy generally respond to bolus doses of diazepam, which results in a brief period of sedation followed by recrudescence of their AWS. However, the dose range and other sedative-hypnotics required to achieve this may be dramatically different than what is observed in subjects with nonresistant AWS. In a recent study, use of escalating bolus doses of diazepam, up to 200 mg as an individual dose, combined with phenobarbital in subjects with continued benzodiazepine resistance (defined as the

requirement for bolus doses more frequently than every hour), reduced the need for mechanical ventilation by nearly 50%.²⁸ In non-ICU settings, the ability to administer frequent intravenous doses of diazepam is limited, and the use of intravenous infusions with a second sedative-hypnotic may be more practical.

In instances of extreme benzodiazepine resistance, patients often receive a second GABAergic drug because of “failure” of benzodiazepine therapy. Phenobarbital, given in combination with a benzodiazepine, in intravenous doses of up to 260 mg, is a reasonable choice.²⁸ Caution is required to avoid stacking doses of phenobarbital, as the onset of clinical effect takes approximately 20 to 40 minutes.³⁷ Alternatively, propofol in standard doses may be administered. Although propofol has a rapid onset, it is difficult to titrate, and high-dose or long-term use is associated with profound metabolic consequences.¹⁶ However, in an observational study, propofol was safely administered to 21 subjects intubated for severe benzodiazepine-resistant DTs.²⁸ The main drawback to the use of these drugs is their narrow therapeutic index, with the potential for profound respiratory depression. This is especially true for propofol, which should generally only be used in the setting of mechanical ventilation. Both these sedative-hypnotics can act synergistically with benzodiazepines to enhance GABA-induced chloride channel opening. In addition, propofol uniquely antagonizes NMDA receptors, thus reducing the excitatory component of AWS.

Ethanol

Ethanol consumption is a common and effective means by which alcoholics can self-medicate to treat and/or prevent mild alcohol withdrawal. Consequently, some hospitals still administer ethanol for either prophylaxis and/or treatment of AWS. In one survey, 72% of 122 hospitals surveyed had administered either intravenous or oral ethanol for these indications.⁹ Despite its widespread use, little randomized controlled data supports its use. In one trial, 39 trauma patients without hepatic or CNS disease were successfully treated with 10% ethanol infusion for treatment of presumed AWS.¹⁷ Conversely, intravenous ethanol was no more effective than flunitrazepam in one trial and inferior to diazepam in another in the prevention of AWS in postoperative surgical patients.^{22,74} Although the authors did not report any adverse effects in these trials, the necessity for frequent blood alcohol monitoring, unpredictable elimination kinetics, potential for significant hepatic complications, the postulated adverse effects of ethanol on wound healing, and the difficulty in safely administering this therapy makes it inappropriate to recommend this regimen.³³

Adrenergic Antagonists

Numerous studies have investigated the use of sympatholytics to control the autonomic symptoms of alcohol withdrawal. Both β -adrenergic antagonists and clonidine reduced blood pressure and heart rate in randomized, placebo-controlled trials.^{7,44} However, the inability of these xenobiotics to address the underlying pathophysiologic mechanism of AWS and subsequently control the neurologic manifestations makes them suboptimal as the sole therapeutic. There are additional concerns. By altering the physiologic parameters that serve as classic markers for AWS severity, there is a risk of underadministering necessary amounts of benzodiazepines.⁸⁰ This was observed in a randomized controlled trial of the central α -agonist lofexidine,⁴⁰ and it is particularly complicated if using the peripheral findings to assess severity as is done with CIWA. Finally, there are a growing number of reports documenting the use of the central α -adrenergic agonist, dexmedetomidine, for AWS in both animals and humans. A recent large, observational study demonstrates that dexmedetomidine is effective at reducing blood pressure and heart rate in patients with AWS, with a significant reduction in the amount of lorazepam required.⁵⁷ However, the study failed to document a change in overall treatment duration, and CIWA scores were not recorded. Consequently, given the high cost of dexmedetomidine, we do not recommend using this drug for the treatment of AWS until it becomes clear that other standard therapies have failed.

Magnesium

The theoretical benefits of magnesium supplementation are based both on the high prevalence of magnesium deficiency in alcoholics and its usefulness in preventing seizures in other disorders, including eclampsia.³⁴ Furthermore, magnesium deficiency has many clinical similarities to AWS, clouding the differential diagnosis. Numerous studies have evaluated the efficacy of magnesium supplementation. However, in a randomized, placebo-controlled trial, magnesium had no effect on either the incidence of withdrawal seizures or severity of alcohol withdrawal.⁷⁷ Consequently, aside from repletion of electrolyte abnormalities, there is no indication for routine administration of magnesium for the treatment of AWS. However, because hypomagnesemia is common and may worsen with glucose, water, and thiamine, it should be routinely screened with both blood and ECG (QT) and supplemented as needed.

Anticonvulsants

Carbamazepine has been used in multiple trials for treatment of mild AWS, more commonly in Europe where an intravenous preparation is available. In animal studies, carbamazepine increases both the CNS GABA concentrations and

the seizure threshold in alcohol withdrawal models. However, there are insufficient data to recommend the use of carbamazepine in humans.^{6,50} Valproic acid appears to have a benzodiazepine-sparing effect in patients with mild withdrawal, but the true clinical benefit is unclear.¹ In contrast, a recent randomized placebo-controlled study of the newer anticonvulsant, oxcarbazepine, showed no difference between this xenobiotic and placebo in inpatient detoxification.⁴¹ Consequently, while this class of drugs may be reasonably recommended as adjuncts, they should not be used as monotherapy for treatment of moderate or severe AWS.

SUMMARY

- Alcohol withdrawal is a complex physiologic process involving both enhanced neuronal excitation and reduced inhibition resulting in neuroexcitation.
- The manifestations of greatest concern are neurologic and include altered mental status and seizures, but the autonomic excess may be clinically consequential.
- Treatment includes supportive care and sedation with benzodiazepines in escalating doses.
- When benzodiazepines cannot produce adequate sedation, sedative-hypnotics such as phenobarbital or propofol should be added.

82 HALLUCINOGENS

Jennifer L. Carey and Kavita M. Babu

HISTORY

A “hallucination” may be defined as a false perception that has no basis in the external environment. The term is derived from the Latin term meaning “to wander in mind.” While the term “psychedelic” has been used for years to refer to the recreational and nonmedical effects of hallucinogens, other terms, like entheogen and entactogen, frequently appear in Internet discussions. Entheogens are “substances which generate the god or spirit within,” while entactogens create an awareness of “the touch within.”⁴¹ These terms all refer to the same xenobiotics, used with differing intent or in varying settings. Hallucinations differ from illusions, which are distorted perceptions of objects based in reality.

Hallucinogens are a diverse group of xenobiotics that alter and distort perception, thought, and mood without clouding the sensorium. Hallucinogens can be categorized by their chemical structures, and further divided into natural and synthetic members of each family. The major structural classes of hallucinogens include the lysergamides, tryptamines (indolealkylamines), amphetamines (phenylethylamines), arylhexamines, cannabinoids, harmine alkaloids, belladonna alkaloids, and the tropane alkaloids. In addition, there are several unique hallucinogens, such as *Salvia divinorum*, nutmeg, kratom, and kava kava. This chapter focuses on lysergamides, tryptamines, phenylethylamines, and the unique hallucinogens. More on the other classes can be found in [Chaps. 76, 77, 78, and 86](#).

Hallucinogens have been used for thousands of years by many different cultures, largely during religious ceremonies. The ancient Indian holy book, *Rig-Veda*, written more than 3500 years ago, describes a sacramental substance called Soma both as a god and as an intoxicating substance. Although debated for many years, the source of Soma is now believed to be an extract of the mushroom *Amanita muscaria*.^{101,108} The Aztecs used the psilocybin-containing *teonanacatl* (flesh of the gods) and *Ololiuqui* (morning glory species) in their religious ceremonies. To this day, the Native American Church in the United States uses peyote in religious ceremonies.

From medieval times through recent years, several large-scale epidemics of vasospastic ischemia, gangrene, and hallucinations (collectively called ergotism) have resulted from *Claviceps purpurea* contamination of cereal crops.¹³⁶ The hallucinations from *Claviceps* ingestion are attributed to the ergot alkaloid lysergic acid amide from which lysergic acid diethylamide (LSD) was chemically synthesized. *Claviceps purpurea* has been suggested, but subsequently disproved, as the cause of the mass hysteria leading up to the Salem witch trials. Many of these adverse effects after ingestion of *C. purpurea* have been attributed to the serotonergic agonist effects of the ergot alkaloids ([Chap. 54](#)).³⁸

Synthetic hallucinogen use is often said to have begun in 1938 when Albert Hofmann, a Swiss chemist, synthesized LSD while performing extensive research on the medicinal uses of ergot alkaloids derived from the fungus, *C. purpurea*. Five years later, LSD was “tested” when Hofmann exposed himself in his laboratory and subsequently developed hallucinations.^{63,120} Soon thereafter, Sandoz Laboratories began marketing LSD under the trademark *Delysid* as an adjunct for analytic psychotherapy. In the 1950s, a small number of psychiatrists began using LSD to release the repressed memories of patients, and as an experimental model for schizophrenia.¹²⁷ The US Central Intelligence Agency reportedly experimented with the use of LSD as a tool for interrogating suspected communists and as a mind-control agent.^{23,120}

In the 1960s, the concept of the “fifth freedom” emerged. As individuals explored this “right” to alter their consciousness as they saw fit, LSD (also called acid) became a fashionable recreational drug. In one of the most famous slogans of the 1960s, Dr. Timothy Leary popularized LSD as a way to “Tune in, Turn on, Drop out.”¹²⁰ By 1966, US federal law banned the use of LSD.⁹⁴ Initial reports of LSD-induced chromosomal damage appeared in the 1960s.^{32,65,76} However, further studies of pregnant women who had taken LSD did not demonstrate an increased risk of abortions or birth defects.^{44,73}

LSD use diminished in the late 1970s and early 1980s, perhaps due to user concerns regarding potential health risks of brain damage, “bad trips” and flashbacks.¹⁰⁰ In the meantime, there was a rise in the use of the “designer” hallucinogens. Exploiting a loophole in drug enforcement laws, these designer synthetic tryptamine and amphetamine hallucinogens are chemically similar to, but legally distinct from, their outlawed counterparts and therefore not subjected to legislative drug control. These are often referred to as “legal highs.” The Internet has developed as a vehicle for the rapid and facile sharing of information on the synthesis of emerging drugs, user experiences, and adverse effects. Additionally, the Internet

marketplace has made many “herbal” hallucinogens widely available via unregulated Web sites.³⁶ All-night dance clubs host “rave parties,” at which emerging hallucinogens are popular.¹³ While the impact of these parties on the growth of hallucinogens in the United States is unclear, many of the newer hallucinogens have been christened “club drugs” because of this association.⁵³

Resurgence in LSD use was reported among high school teens in the late 1990s, with more prevalent use in the suburbs than the city.^{95,109} In 1997, two studies of adolescents showed a lifetime prevalence of LSD use at 13% and 14%.^{67,100} In 2000, US Drug Enforcement Agency (DEA) agents seized an LSD-production lab and apprehended two men involved in massive production of LSD in Kansas City. Their incarceration resulted in a more than 90% decrease in LSD availability nationwide.

While much of the research involving psychedelic drugs was halted in the 1960s, there has been a reemergence of clinical investigations since the late 1980s for the treatment of various psychiatric disorders, with emphasis on treatment of anxiety and addictions. Recently, psilocybin has been evaluated for the treatment of the existential anxiety associated with end-stage cancer and obsessive-compulsive disorders, while 3,4-methylenedioxymethamphetamine (MDMA) has been studied as an adjunct to psychotherapy for treatment-resistant posttraumatic stress disorder.^{57,89,90} The clinical or research use of psychedelic drugs remains highly controversial.

EPIDEMIOLOGY

The 2006 National Survey on Drug Use and Health (NSDUH) reported the following trends in hallucinogen use: more than 23 million Americans older than 12 years of age reported LSD use during their lifetime, 6.6 million had used phencyclidine (PCP), and 12 million reported previous MDMA use. Additionally, 2.3 million people reported prior use of ketamine, while only 700,000 reported use of α -methyltryptamine (AMT), dimethyltryptamine (DMT), or 5-methoxydimethyl tryptamine (5-MeO-DMT). About 1.8 million people reported use of *Salvia divinorum* during their lifetime. In the reported results, the 18 to 25 year-old age group was most likely to report use of any of these hallucinogens within the previous year (Table 82–1).¹²² In 2010 the NSDUH reported that 1.2 million Americans older than 12 years of age were current users of hallucinogens.¹²⁸

TABLE 82–1. Structural Classifications of Hallucinogens

Lysergamides

- D-Lysergic acid diethylamide

- Lysergic acid hydroxyethylamide

 - Morning glory (*Ipomoea violacea*)

 - South American morning glory (*Ololiuqui*)

- Ergine

 - Woodrose (*Argyrea nervosa*)

Indolealkylamines/tryptamines

- 5-Methoxy-*N,N*-dimethyltryptamine (5-MeO-DiPT, Foxy Methoxy)

- N,N*-dimethyltryptamine

- Psilocybin

Phenylethylamines

- Mescaline

- 3,4-Methylenedioxymethamphetamine (MDMA)

- 2C-B

- 2C-T-7

Tetrahydrocannabinoids

- Marijuana

- Hashish

Belladonna alkaloids

- Jimsonweed (*Datura stramonium*)

- Henbane (*Hyoscyamus niger*)

- Deadly nightshade (*Atropa belladonna*)

- Brugmansia* spp

Miscellaneous

- Kava kava

- Ketamine

- Kratom

- Nutmeg

- Phencyclidine (PCP)

- Salvia divinorum*

LYSERGAMIDES

Lysergamides are derivatives of lysergic acid, a substituted tetracyclic amine based on an indole nucleus (Fig. 82–1).

Naturally-occurring lysergamides are found in several species of morning glory (*Rivea corymbosa*, *Ipomoea violacea*) and Hawaiian baby woodrose (*Argyrea nervosa*).⁵⁹ Morning glory seeds contain multiple alkaloids, including lysergic acid, hydroxyethylamide, and ergonovine. Morning glory seeds were called *ololiuqui* in ancient Mexico, where Aztecs and other indigenous populations used them in religious rites.¹²⁴ However, in one volunteer study, *ololiuqui* caused sedation rather than hallucinations.⁶⁴ Hawaiian baby woodrose seeds contain ergine. Both morning glory and Hawaiian baby woodrose seeds can be legally purchased for planting in garden stores and on the Internet.

FIGURE 82–1. Hallucinogens of the lysergamide chemical class and their chemical similarity to serotonin.

The synthetic lysergamide, LSD, is derived from an ergot alkaloid of the fungus, *Claviceps purpurea*. Although four LSD isomers exist, only the d-isomer is active. Lysergic acid diethylamide is a water-soluble, colorless, tasteless, and odorless powder. Currently, LSD is typically sold as liquid-impregnated blotter paper, microdots, tiny tablets, “window pane” gelatin squares, liquid, powder, or tablets.¹⁰⁹ LSD users typically experience heightened awareness of auditory and visual stimuli with size, shape, and color distortions. Auditory and visual hallucinations may occur, as well as synesthesia, a confusion of the senses, where users may report “hearing colors, or seeing sounds.” Other more complex perceptual effects may include depersonalization and a sensation of enhanced insight or awareness. A “bad trip” is said to occur when LSD use produces anxiety, bizarre behaviors, and combativeness.

LSD is classified by the DEA as a Schedule I agent, with high abuse potential, lack of established safety even under medical supervision, and no known use in medical treatment.

INDOLEALKYLAMINES (TRYPTAMINES)

Indolealkylamines, or tryptamines, represent a class of natural and synthetic compounds that structurally share a substituted monoamine group (Fig. 82–2). Endogenous tryptamines include serotonin and melatonin. Naturally occurring exogenous tryptamines include psilocybin, bufotenine, and DMT. Psilocybin is found in three major genera of mushrooms: *Psilocyba*, *Panaeolus*, and *Conocybe*.¹⁰⁸ Other psychoactive mushrooms include *Amanita muscaria* and *Amanita pantherina*, which contain ibotenic acid, muscimol, and muscazone, which are unrelated to the tryptamines.⁵⁹ Hallucinogenic mushrooms are discussed at length in Chap. 120. Psilocybin-containing mushrooms, or “magic mushrooms,” grow in the Pacific Northwest and southern United States, usually in cow pastures. The mushroom may be recognized by a green-blue color that it assumes after bruising, but misidentification is common.¹¹

FIGURE 82–2. Hallucinogens of the indolealkylamine chemical class and their chemical similarity to serotonin.

N,N-dimethyltryptamine (DMT) is a potent short-acting hallucinogen found naturally in the bark of the Yakee plant (*Virola calophylla*), which grows in the Amazon basin. It is used by shamans as a hallucinogenic snuff to “communicate with the spirits.”¹⁰⁸ DMT is also found in the hallucinogenic tea, ayahuasca, which is used by indigenous healers in the Amazon Basin. In ayahuasca, DMT-containing plants (eg, *Psychotria viridis*) are combined with plants containing harmine alkaloids (eg, *Banisteriopsis caapi*), which inhibit hepatic monoamine oxidases to increase the oral bioavailability of DMT (Chap. 73).⁸⁵

The use of toads in religious ceremonies and witchcraft dates back thousands of years. All species of the toad genus *Bufo* have parotid glands on their backs that produce a variety of substances, including dopamine, epinephrine, and serotonin.⁷⁸ Some of these toads produce bufotenine, a tryptamine, which causes hypertension, but does not cross the blood–brain barrier. Interest in bufotenine grew out of reports of a toad-licking fad in the 1980s, in which individuals would reportedly lick toads for recreational purposes.⁷⁷ However, further review suggests that bufotenine is not the hallucinogenic substance found in toad secretions. Instead, 5-MeO-DMT has been identified as the psychoactive substance.¹³⁵ 5-MeO-DMT is only found in one species of toad, *Bufo alvarius* (Sonoran Desert toad or Colorado River toad).⁷⁷ Although bufotenine has been classified as a Schedule I substance by the DEA for many years, 5-MeO-DMT was not scheduled until 2009.⁹¹ Like DMT, 5-MeO-DMT is rapidly metabolized by intestinal monoamine oxidase enzymes; oral ingestion of toad venom or skins would thus have limited potential as a route of recreational use.²¹ Methods for extracting and drying *B. alvarius* secretions for smoking and insufflation are available on the Internet. Death has resulted from wrongful use of *Bufo* secretions for purposes of aphrodisia.^{30,55} The toad venom glands also produce cardioactive steroids, called bufadienolides, which cause digoxinlike cardiac toxicity, and in some species, can secrete tetrodotoxin.^{87,139}

Two of the more important synthetic tryptamines include N,N-diisopropyl-5-methoxytryptamine (5-MeO-DiPT, Foxy Methoxy) and α -methyltryptamine (AMT, IT-290). Since 2001, law enforcement authorities in more than 10 states have seized large amounts of 5-MeO-DiPT and AMT. These drugs are often sold surreptitiously as MDMA. 5-MeO-DiPT received Schedule I status in 2004.¹³⁰ α -Methyltryptamine (AMT or IT-290) is a monoamine oxidase inhibitor that was sold as an antidepressant in the former Soviet Union.¹¹⁴ AMT was placed into Schedule I status by the DEA in September 2004.¹³⁰

PHENYLETHYLAMINES (AMPHETAMINES)

Dopamine, norepinephrine, and tyrosine are endogenous phenylethylamines. Exogenous phenylethylamines stimulate catecholamine release and cause a variety of physiologic and psychiatric effects, including hallucinations. Substitution on the phenylalkylamine structure has important effects on both the hallucinogenic and stimulant potential of the drug. The presence of a methyl group in the side chain of the phenylethylamines is associated with a higher degree of hallucinogenic effect (Fig. 82–3).⁶⁹ MDMA, amphetamine, and methamphetamine are well known members of this family and are discussed in detail in Chap. 76.

FIGURE 82–3. Hallucinogens of the phenylethylamine chemical class.

The best recognized of the naturally occurring psychoactive phenylethylamines is mescaline. Mescaline is found in Peyote (*Lophophora williamsii*), a small blue-green spineless cactus that grows in dry and rocky slopes throughout the southwestern United States and northern Mexico. Peyote buttons are the round, fleshy tops of the cactus that are sliced off and dried. The legal use of peyote in the United States is restricted to members of the Native American Church, for whom peyote buttons are used for both religious ceremonies and medical treatment for physical and psychological ailments.^{24,27}

Other nonindigenous cactus species containing significant amounts of mescaline include the San Pedro cactus (*Trichocereus pachanoi*) and Peruvian torch cactus (*Trichocereus peruvianus*). These plants can be purchased for ornamental purposes in garden stores and on the Internet.⁵⁹

The synthesis and effects of hundreds of other congeners of amphetamine is well described.¹¹³ Included are the synthetic hallucinogenic amphetamines 4-bromo-2,5-dimethoxyphenethylamine (2C-B, Nexus, Bromo, Spectrum) and 2,5-dimethoxy-4-N-propylthiopheneethylamine (2C-T-7, Blue Mystic).

During the 1980s, 2C-B gained popularity as a legal alternative to MDMA. When 2C-B was given Schedule I status in 1995, 2C-T-7 emerged as another legal designer amphetamine.⁹ In March 2004, 2C-T-7 also received Schedule I status.³⁴

SALVIA DIVINORUM

Salvia divinorum is a perennial herbaceous member of the mint family. While there are more than 500 species of *Salvia*, *S. divinorum* is most recognized for its hallucinogenic properties.¹³¹ *Salvia divinorum* is a native to areas of Oaxaca, Mexico, and grows well in sunny temperate climates. Plants, leaves, and extracts may be purchased online, and tips for cultivation of plants are easily accessible.

Since the sixteenth century, the Mazatec Indians have used *S. divinorum* as a hallucinogen in religious rites as a means of producing “visions.”¹³¹ The Mazatecs continue to revere *S. divinorum* as an incarnation of the Virgin Mary, referring to the plant as “ska Maria.” Currently, although the federal Controlled Substances Act does not prohibit use of *S. divinorum* or

its psychoactive extracts, the possession and sale of *S. divinorum* is illegal in several states, including Delaware, Florida, and Georgia. Nationwide regulation of this substance exists in Australia, and there is local regulation in some municipalities where *S. divinorum* use among teenagers is rampant.¹²⁹ There continues to be widespread marketing of this hallucinogen on the Internet as a “legal hallucinogen.”

KRATOM

Kratom, or *Mitragyna speciosa* Korth, is derived from the leaves of a tree native to Asia and Africa.¹¹² Kratom has dual properties, producing stimulant effects and opioidlike analgesic effects. It was used in Southeast Asia to enhance productivity in manual laborers. The Kratom alkaloids mitragynine and 7-hydroxymitragynine activate μ -, δ -, and δ -opioid receptors. It has been used as a substitute for opium, although hallucinogenic effects are uncommon, they are reported following heavy use.¹²³ Kratom has been illegal in Thailand since 1946 and in Australia since 2005. Kratom is currently legal to possess and use in the United States, where it has been adopted by some patients for self-treatment of chronic pain and to modulate opioid withdrawal symptoms.

NUTMEG

Nutmeg is derived from *Myristica fragrans*, an evergreen tree native to the Spice Islands. The fruits of the tree contain a central kernel called the nutmeg, while the surrounding red aril is used to produce a spice called mace.⁹⁹ While nutmeg is commonly available as a cooking spice, it has been used medicinally for centuries as an antidiarrheal and abortifacient.⁵⁸ It is a recreational herbal that has also been used to produce euphoria and hallucinations; it is more likely to be abused by adolescents due to its low cost and accessibility.^{35,99,105}

BELLADONNA ALKALOIDS

The belladonna alkaloids, including the tropane alkaloids atropine, hyoscyamine, and scopolamine, can be isolated from a number of plants. Deadly nightshade (*Atropa belladonna*), a perennial plant, grows throughout the United States, as well as in areas of Europe and Africa. Belladonna alkaloids can be isolated from both the leaves and berries of this perennial plant. Jimson weed (*Datura stramonium*), also called locoweed, grows throughout warm and moist areas of the world. This bush contains pods full of small black seeds that are ingested or brewed as a tea for their hallucinogenic properties. The common name Angel’s trumpet is used for plants of the Solanaceae family with large trumpet-shaped white flowers (*Brugmansia* or *Datura*). Given their wide availability, in the wild and over the Internet, these plants are frequently used as hallucinogens by adolescents.⁵⁴ Unfortunately, they produce significant morbidity from anticholinergic toxicity in unwary users. Moonflower, a common name given to several plants, including *Datura innoxia*, was responsible for anticholinergic poisoning of more than a dozen adolescents in one series.³¹ Additionally, epidemics of unintentional poisoning were reported among drug users who received heroin adulterated with scopolamine.⁶¹

TOXICOKINETICS

LSD is the most studied hallucinogen, and there is extensive information about its pharmacokinetics (Table 82–2). Ingestion is the most common route of exposure, and the gastrointestinal tract rapidly absorbs LSD. Other reported routes of administration include intravenous, intramuscular, intranasal, parenteral, sublingual, inhalation, and conjunctival instillation. Plasma protein binding is more than 80% and volume of distribution is 0.28 L/kg. It is concentrated within the visual cortex as well as the limbic and reticular activating systems. It is metabolized in the liver via hydroxylation and glucuronidation, and excreted predominantly as a pharmacologically inactive compound. LSD has an elimination half-life of about 2.5 hours. Only small amounts are eliminated unchanged in the urine. The minimum effective oral dose is 25 μ g.⁷⁰ The onset of effects may occur 30 to 60 minutes after exposure, with a duration of 10 to 12 hours.

TABLE 82–2. Pharmacology of Selected Hallucinogens

Drug Name or Source	Psychoactive Component (if Different)	Typical Oral Dose	Onset	Duration
Bufo species toads	5-MeO-DMT	5–15 mg (smoked)	Immediate (smoked)	5–20 minutes (smoked)
DMT	–	15–60 mg	5–20 minutes	30–60 minutes
"Foxy Methoxy"	5-MeO-DiPT	6–10 mg	20–30 minutes	3–6 hours
Woodrose (<i>Argyreia nervosa</i>)	Ecgonine	5–10 seeds	minutes	6–8 hours
Jimson weed (<i>Datura stramonium</i>)	Atropine, hyoscyamine, scopolamine	10 seeds	20–30 minutes	2–3 hours
Kratom (<i>Mitragyna speciosa</i> Korth)	Mitragynine, 7-Hydroxy-mitragynine	2–6 g (stimulant); >7 g (sedative)	10–15 minutes	4–6 hours
Lysergic acid diethylamide (LSD)	Lysergic acid diethylamide	50–100 µg	30–60 minutes	10–12 hours
"Magic mushrooms" (<i>Psilocybe</i> species)	Psilocybin, psilocin	5 g mushrooms	30 minutes–2 hours	4 hours
Nutmeg (<i>Myristica fragrans</i>)	Myristicin, elemicin	20 g	1 hour	24 hours
Peyote (<i>Lophophora williamsii</i>)	Mescaline	6–12 buttons, 270–540 mg mescaline	1–3 hours	10–12 hours
<i>Salvia divinorum</i>	Salvinorin A	–	30 minutes (inhaled); 1 hour (oral)	15–20 minutes (inhaled); 2 hours (oral)
2C-B	–	16–30 mg	1 hour	6–10 hours

Ingestion of 200 to 300 morning glory seeds is required to achieve hallucinogenic effects. Only 5 to 10 seeds of Hawaiian baby woodrose are required to produce hallucinations. After ingestion of woodrose seeds, the effects typically last for 6 to 8 hours and produce tranquility without marked euphoria.⁴

Peyote buttons are very bitter, and can be eaten whole or dried and crushed into a powder, which is reconstituted as tea.⁵⁹ Nausea, vomiting, and diaphoresis often precede the onset of hallucinations, which begin at 1 to 3 hours postingestion, and last for up to 12 hours.⁹⁹ Six to twelve peyote buttons, or 270 to 540 mg of mescaline, are commonly required to produce hallucinogenic effects.¹⁰⁷ Ingestion of up to 5 g of psilocybin-containing mushrooms may be required to produce hallucinogenic effects. After ingestion of *Psilocybe* mushrooms, psilocybin is converted to psilocin, the active hallucinogen in the gastrointestinal tract.⁵⁶ The effects of psilocin are similar to LSD, but with a shorter duration of action of about 4 hours.

For recreational purposes, DMT is typically smoked, snorted, or injected. Hallucinogenic effects peak in 5 to 20 minutes, with a duration of 30 to 60 minutes, earned DMT the nickname the "businessman's trip." 5-MeO-DiPT is most commonly ingested, but may be smoked or insufflated. Effects begin 20 to 30 minutes after ingestion, and include disinhibition and relaxation. There is a dose-dependent response and at higher ranges, symptoms include mydriasis, euphoria, auditory and visual hallucinations, nausea, diarrhea, and jaw clenching.^{93,115} The hallucinogenic effects are reported to last from 3 to 6 hours.^{86,115} Other substances may be used to heighten or prolong the hallucinogenic effects of 5-MeO-DiPT. These include sildenafil, γ -hydroxybutyrate, benzodiazepines, and marijuana. AMT is available as a white powder, which may be ingested, smoked, or insufflated. Hallucinations typically occur within 30 minutes, but may last 12 to 16 hours.⁷⁵

Amphetamine, methamphetamine, and MDMA are well absorbed through the gastrointestinal tract. The elimination half-life ranges from 8 to 30 hours for members of this class and is dependent on urine pH.^{12,33} Amphetamines are weak bases and undergo more rapid elimination in acidic urine.¹¹⁰ The volume of distribution ranges from 3 to 5 L/kg for amphetamine, 3–4 L/kg for methamphetamine, and likely more than 5 L/kg for MDMA.^{12,33,74,110} Elimination of other amphetamines occurs through multiple mechanisms including aromatic hydroxylation, aliphatic hydroxylation, and N-dealkylation.⁷⁴ Tolerance occurs with chronic amphetamine use.⁷¹

There is little information about 2C-B and 2C-T-7 in the medical literature. Both drugs may be used via oral, intranasal, and intrarectal routes. Both 2C-B and 2C-T-7 exert their hallucinogenic effects within one hour of use, and physiologic and psychologic effects may persist for 6 to 10 hours. Additional information on the kinetics of amphetamine and congeners may be found in [Chap. 76](#).

Salvia divinorum may be chewed, smoked, or ingested as tea. Hallucinations occur immediately after exposure to the

drug and are typically quite vivid. Synesthesia is reported among *Salvia* users. Hallucinogenic effects after *S. divinorum* use are typically brief, lasting only 1 to 2 hours. Pharmacokinetic data for *S. divinorum*, and its primary psychoactive, Salvinorin A, were described in one volunteer study.¹¹⁶ Psychoactive effects were typically experienced 5 to 10 minutes after absorption of Salvinorin A via the buccal mucosa, reaching a plateau during the first hour after exposure and resolving within 2 hours. Vaporization and inhalation of Salvinorin A led to more rapid effects beginning at 30 seconds after exposure. These effects would plateau at 5 to 10 minutes and typically subside after 20 to 30 minutes. In this study, ingestion of *S. divinorum* leaves did not produce the same effects as buccal or inhalational administration, leading to the theory that gastrointestinal deactivation of Salvinorin A occurs after ingestion.¹¹⁶

Kratom leaves can be decocted into tea, chewed, or smoked.⁶⁶ Kratom leaves contain approximately 0.8% mitragynine by weight, but can vary by geographic origin of trees, as well as season.¹¹¹ Neuropsychiatric effects are dose dependent and occur within 5 to 10 minutes of exposure, with effects lasting 4 to 6 hours.¹²³ Stimulant effects predominate at doses of 2 to 6 g, while sedation becomes more pronounced at doses above 7 g.

Nutmeg is usually ingested as a paste, or mixed in a beverage; 15 to 20 g of the substance is required for clinical effects.⁹⁹ This dose is often unpalatable, and a case report of recreational use of encapsulated nutmeg has been described.¹⁰⁵ Clinical effects can begin 1 hour after nutmeg ingestion; nausea and vomiting precede the onset of hallucinations, and effects can persist for more than 24 hours after exposure.⁹⁹

The belladonna alkaloids are most concentrated in the seeds of Jimson weed; each seed contains approximately 0.1 mg of atropine.¹¹⁸ Ingestion of as few as 10 seeds can produce hallucinations within 20 to 30 minutes; these effects can last for 2 to 3 hours. While the roots and seeds of Angel's trumpet contain the highest alkaloid concentrations, users most often brew the blossom into a tea. Each blossom contains approximately 0.3 mg of atropine and 0.65 mg of scopolamine.⁵⁴ The elimination half-lives of atropine and hyoscyamine are 2.5 and 3.5 hours, respectively, while the elimination half-life of scopolamine is considerably longer, at 8 hours.¹⁵

PHARMACOLOGY

Although the lysergamide, indolealkylamine, and phenylethylamine hallucinogens are structurally distinct, the similarities in their effects on cognition support a common site of action on central serotonin receptors.^{3,20,26,62,126} Serotonin (5-HT) modulates many psychological and physiologic processes, including mood, personality, affect, appetite, motor function, sexual activity, temperature regulation, pain perception, sleep induction, and ADH release. There are more than 14 known 5-HT receptor subtypes (Chap. 14); differing affinity for these subtypes occurs based on the structure of the hallucinogen, and may account for the subtle differences between their effects.

The lysergamide, indolealkylamine, and phenylethylamine hallucinogens all bind to the 5-HT₂ class of receptors. There is good correlation between the affinity of both indolealkylamine and phenylethylamine hallucinogens for 5-HT₂ receptors in vitro and hallucinogenic potency in humans.^{3,52,98,126} The 5-HT_{2A} receptor subtype appears to have the highest density in the cerebral cortex and may represent the binding site for hallucinogens.⁸⁰ This is bolstered by an animal study that shows that a selective 5-HT_{2A} antagonist can inhibit the effects of LSD and a phenylethylamine, 2,5-dimethoxy-4-iodo-amphetamine (DOI). The response to high doses of LSD and DOI suggest that both lysergamides and phenylethylamines are partial agonists at cortical 5-HT_{2A} receptors.^{51,80,104}

Although most investigations have focused on the role of serotonin for drug-induced hallucinations, other neurotransmitters are also involved. Stimulation of 5-HT_{2A} receptors enhances release of glutamate in the cortical layer V pyramidal cells.^{3,8} LSD and other lysergamides stimulate both D₁ and D₂ dopamine receptors.^{7,50,134} In animal models, LSD and phenylethylamine hallucinogens modulate NMDA receptor-mediated effects and may have a protective effect against neurotoxicity secondary to PCP and ketamine.^{8,43}

Another theory that incorporates these other neurotransmitters involves the concept of "thalamic filtering."⁴⁹ The thalamus receives input and output from the cortex and reticular activating system, and functions to filter relevant sensory input. This theory has been explored as an explanation for organic psychosis and the effects of hallucinogenic drugs. Multiple neurotransmitters, including dopamine, acetylcholine, GABA, and glutamate, exert their actions on the thalamus. Increased excitatory or decreased inhibitory neurotransmitter in this region of the brain may lead to "sensory overload," which manifests itself clinically as symptoms of psychosis.⁴⁹ Experimental evidence also demonstrates EEG abnormalities after administration of hallucinogens, confirming a cortical, rather than the ophthalmologic, etiology for hallucinations.⁴²

Salvinorin A, the psychoactive component of *Salvia divinorum*, is one of the most potent natural hallucinogens. The effect of Salvinorin A occurs via binding at the δ -opioid receptor, making it structurally and mechanistically unique (Fig. 82-4).¹³⁸ The δ -opioid receptor is distinct from the μ opioid receptor, a stimulation that generally causes euphoria and analgesia (Chap. 38). Salvinorin A does not demonstrate any known serotonergic activity.¹³⁸

FIGURE 82–4. Structure of Salvinorin A.

The opioid effects of Kratom have been attributed to mitragynine.^{111,137} The most prevalent of the Kratom alkaloids, mitragynine shares a structural similarity with yohimbine.¹⁰ In vitro, mitragynine is active at both supraspinal opioid δ - and μ -receptors.¹²⁵ This μ -receptor activity results in analgesia and efficacy in treating opioid withdrawal symptoms. Additionally, mitragynine activates noradrenergic and serotonergic pathways.⁸³ Another Kratom alkaloid, 7-hydroxymitragynine, also demonstrates antinociceptive effects and high affinity for opioid receptors.⁸⁴ In animal studies, 7-hydroxymitragynine has more analgesic potency than morphine, even after oral administration.⁸²

Nutmeg contains a number of purportedly psychoactive compounds, including myristicin, elemicin, and safrole (Fig. 82–5). The psychoactive components of nutmeg include terpenes and alkyl benzyl derivatives (myristicin, elemicin, and safrole).⁹⁹

FIGURE 82–5. Structure of myristicin.

It is theorized that the aromatics found in nutmeg are metabolized to amphetaminelike compounds that create hallucinogenic effects.⁹⁹ However, this mechanism is unsupported by both theory and animal data.¹⁰⁵ Nutmeg contains myristicin and elemicin, both weak monoamine oxidase inhibitors that also demonstrate serotonergic activity, which may account for the clinical effects of nutmeg.¹⁰⁵

The pharmacology of atropine, a competitive central and peripheral antimuscarinic, and the most well studied belladonna alkaloid, is discussed in detail in Antidotes in Depth: A32. Like atropine, scopolamine and hyoscyamine are tertiary amines, which can cross the blood–brain barrier. Scopolamine causes more sedation than atropine, and its transdermal availability has led to its use in motion sickness patches. Hyoscyamine is more potent than atropine; it has traditionally been used as an antispasmodic for gastrointestinal conditions.

CLINICAL EFFECTS

Physiologic changes accompany and often precede the perceptual changes induced by lysergamides, tryptamines, and phenylethylamines. The physical effects may be caused by direct drug effect or by a response to the disturbing or enjoyable hallucinogenic experience. Sympathetic effects mediated by the locus coeruleus include mydriasis, tachycardia, hypertension, tachypnea, hyperthermia, and diaphoresis. They may occur shortly after ingestion and often precede the hallucinogenic effects. Other clinical findings that are reported include piloerection, dizziness, hyperactivity, muscle weakness, ataxia, altered mental status, coma, and rhythmic, pupillary dilation, and constriction.⁷² Nausea and vomiting often precede the psychedelic effects produced by psilocybin and mescaline. Potentially life-threatening complications, such as hyperthermia, coma, respiratory arrest, hypertension, tachycardia, and coagulopathy, were described in a report of eight patients with a massive LSD overdose.⁶⁸ Sympathomimetic effects are generally less prominent in LSD toxicity than in phenylethylamine toxicity. Similar sympathetic symptoms are described after the use of 2C-B and 2C-T-7. Low doses of 2C-B and 2C-T-7 may produce hypertension, tachycardia, and visual hallucinations, while elevated doses are associated with shifts in color perception, enhanced auditory, and visual stimulation. Three deaths are associated with 2C-T-7 use; in one case, death may have resulted from seizures or aspiration.^{34,39} An analog of 2C-B, called 2C-B-FLY, or Bromo-

dragonFLY, is implicated in finger necrosis that requires amputation secondary to potent peripheral vasospastic activity as well as sudden cardiac death.⁹⁶ Similar vasoconstrictive effects resulting in limb ischemia may be induced by exposure to ergot containing alkaloids.

The psychological effects of hallucinogens seem to represent a complex and elusive interaction between different neurotransmitters, including the serotonergic and dopaminergic systems. Based on this serotonergic mechanism, serotonin toxicity could theoretically occur after the use of any of the lysergamide, indolealkylamine or phenylethylamine hallucinogens. Animal studies have documented LSD and tryptamine-induced serotonin toxicity.^{117,132} Case reports have linked phenylethylamine use to fatal serotonin toxicity in recreational users.^{92,133}

Tolerance to the psychological effects of LSD occurs within 2 to 3 days with daily dosing, but rapidly dissipates if the drug is withheld for two days. Psychological cross-tolerance among mescaline, psilocybin, and LSD is reported in humans.¹⁴ There is no evidence for physiologic tolerance, physiologic dependence, or a withdrawal syndrome with LSD. Limited cross-tolerance is demonstrated between psilocybin and cannabinoids such as marijuana.²²

Salvia divinorum use results in vivid hallucinations and synesthesia.¹¹⁶ Additionally, its use may cause diuresis, nausea, and dysphoria. These aversive effects may limit its long-term recurrent use.¹⁰

The dual stimulant and sedative properties of Kratom contributed to its traditional use among manual laborers. However, its opioidlike activity has led to a surge in contemporary use as an herbal treatment for opioid withdrawal among patients with chronic pain.^{18,19} Anorexia, weight loss, and insomnia are reported among Kratom addicts. Hyperpigmentation of the cheeks is also described among chronic users.¹²³

Recreational nutmeg use results in the desired effects of euphoria and hallucinations, as well as the adverse effects of nausea, vomiting, dizziness, flushing, tachycardia, and hypotension. Two case reports of fatalities from nutmeg ingestion are reported; however, it is unclear if these deaths truly represent nutmeg toxicity.^{29,119}

The belladonna alkaloids produce classic signs of anticholinergic toxicity, including hyperthermia, tachycardia, mydriasis, flushing, anhidrosis, urinary retention, and ileus. The central effects can include restlessness, hallucinations, agitation, delirium, seizures, and coma.³¹ The psychosis produced by belladonna alkaloids can be profound; in one case, a young man autoamputated his tongue and penis after ingestion of tea made from Angel's trumpet.⁸¹

The vast majority of morbidity from hallucinogen use stems from trauma. Hallucinogen users frequently report lacerations and bruises sustained during their "high." Additionally, dysphoria may drive patients to react to stimuli with unpredictable, and occasionally, aggressive behaviors. Many Internet sites regarding hallucinogen use advise readers to take hallucinogens only while under the supervision of a "sitter."⁴⁰

The psychological effects of hallucinogens are dose related and affect changes in arousal, emotion, perception, thought process, and self-image. The response to the drug is related to the person's mindset, emotions, or expectations at the time of exposure and can be altered by the group or setting.¹ The person experiencing the effects of a hallucinogen is usually fully alert, oriented, and aware that he or she is under the influence of a drug. Euphoria, dysphoria, and emotional lability may occur.

Illusions are common, typically involving distortion of body image and alteration in visual perceptions. Hallucinogen users may display acute attention to details with excessive attachment of meaning to ordinary objects and events. Usual thoughts seem novel and profound. Many people report an intensification of their sensory perceptions such as sound magnification and distortion. Colors often seem brighter with halolike lights around objects. Frequently, hallucinogen users relate a sense of depersonalization and separation from the environment, commonly called an "out-of-body" experience. Synesthesias, or sensory misperceptions, such as "hearing colors," or "seeing sounds" are commonly described. Hallucinations may be visual, auditory, tactile, or olfactory.

Acute adverse psychiatric effects of hallucinogens include panic reactions, psychosis, and major depressive dysphoric reactions. Acute panic reactions, the most common adverse effect, present with frightening illusions, tremendous anxiety, apprehension, and a terrifying sense of loss of self-control.⁴⁶ These psychiatric effects may cause patients to seek care in the emergency department.

LABORATORY

Routine urine drug-of-abuse immunoassay screens do not detect LSD or other hallucinogens. Although LSD can be detected by radioimmunoassay of the urine, confirmation by high-performance liquid chromatography (HPLC) or gas chromatography is necessary. These tests are rarely used in the clinical setting but are commonly available for forensic purposes.^{14,37} False-positive urine immunoassay testing for LSD is reported after exposure to several medications, including fentanyl, sertraline, haloperidol, or verapamil.^{47,102}

Depending on their structure, phenylethylamines may cause positive qualitative urine testing by immunoassay for amphetamines. However, amphetamine drug screening is associated with numerous false positive results, particularly after

the use of cold medications that contain ephedrine, pseudoephedrine, or phenylpropanolamine.¹²¹ Urine immunoassays do not detect 5-Meo-DiPT, DMT, AMT, 2C-T-7, and 2CB, but gas chromatography/mass spectrometry (GC/MS) testing methods for detection of these compounds has been described.¹³⁷

Routine urine drug immunoassay screens do not detect Salvinorin A, mitragynine, or myrsitacin. HPLC and liquid chromatography/mass spectrometry (LC/MS) protocols have been applied to the quantitative analysis of Salvinorin A and B in plant matter and in ex vivo animal studies. GC/MS identified Salvinorin A in urine and saliva obtained after two human volunteers smoked *S. divinorum*.⁹⁷ Myristicin testing is not widely available, but it can be obtained.¹¹⁹

TREATMENT

Most hallucinogen users rarely seek medical attention because they experience only the desired effect of the drug. For any hallucinogen user who does present to the emergency department, initial treatment must begin with attention to airway, breathing, circulation, level of consciousness, and abnormal vital signs. Even in those in whom exposure to a hallucinogen is suspected, the basic approach for altered mental status should include dextrose, naloxone, and oxygen therapy as indicated, as is the vigorous search for other etiologies. Hallucinogens rarely produce life-threatening toxicity. Due to their rapid absorption, gastrointestinal decontamination with activated charcoal is of little value after clinical symptoms appear, and attempts may lead to further agitation. Sedation with benzodiazepines is usually sufficient to treat hypertension, tachycardia, and hyperthermia. The patient with a dysphoric reaction can be placed in a quiet location with minimal stimuli. A nonjudgmental advocate should attempt to reduce patient anxiety, provide reality testing, and remind the individual that a drug was ingested and the effect will wear off in a couple of hours. Physical restraint (without chemical restraint) should be avoided to prevent hyperthermia and rhabdomyolysis. Benzodiazepines remain the cornerstone of therapy for both autonomic instability and dysphoria, as the sedating effect can diminish both endogenous and exogenous sympathetic effects.⁸⁸ Autonomic instability and hyperthermia may be a feature of phenylethylamine use as well as tryptamine use or massive LSD overdose.^{46,68,88} Hyperthermia resulting from agitation or muscle rigidity requires urgent sedation with benzodiazepines and rapid cooling. While central nervous system depression is unlikely to be severe enough to require endotracheal intubation in a patient with a pure hallucinogen exposure, intubation and paralysis may be required in the patient with intractable hyperthermia.¹⁶ Seizures may occur with tryptamine or phenylethylamine use and can be initially treated with benzodiazepines. Seizures may also result from hyponatremia in MDMA users and would necessitate treatment with 3% hypertonic saline (Chaps. 19 and 76).

The treatment of anticholinergic toxicity from the belladonna alkaloids involves several critical components: correction of abnormal vital signs, management of delirium, and rapid intervention for seizures or dysrhythmias. The mainstays of therapy are fluid resuscitation and benzodiazepines; however, physostigmine should be considered as antidotal therapy in cases of belladonna alkaloid poisoning. Conflicting data exist regarding the efficacy of physostigmine in decreasing morbidity and length of hospital stay when compared with benzodiazepines alone.^{25,103} Based on the strength of evidence, physostigmine should be considered in patients with evidence of anticholinergic delirium or agitation if there are no contraindications. More information on physostigmine can be found in Antidotes in Depth: A9.

Morbidity and mortality typically result from the complications of hyperthermia, including rhabdomyolysis and myoglobinuric acute kidney injury, hepatic necrosis, and disseminated intravascular coagulopathy. However, for the most part, hydration, sedation, a quiet environment, and meticulous supportive care will prove adequate to prevent morbidity or mortality in recreational use or overdose.²⁸ Treatment of serotonin toxicity from phenylethylamine use is largely supportive and includes the avoidance of further administration of serotonergic medications. Specific therapy with agents like cyproheptadine may be warranted¹⁷ (Chap. 75).

The role of antipsychotics in controlling hallucinogen-induced agitation is unclear. Haloperidol, risperidone, and ziprasidone may have utility in controlling the acutely agitated patient. However, haloperidol and risperidone may worsen panic and visual symptoms, increasing the incidence of hallucinogen persisting perception disorder (HPPD; see below).² The safety of ziprasidone in hallucinogen users has not yet been reported. While further study on these agents is required, prolonged psychosis may require treatment with long-term antipsychotic therapy.

LONG-TERM EFFECTS

Long-term consequences of LSD use include prolonged psychotic reactions, severe depression, and exacerbation of preexisting psychiatric illness.^{60,106} When LSD was initially popularized, some patients were noted to behave in a manner similar to schizophrenia and required admission to psychiatric facilities. In volunteer studies, panic reactions, HPPD, and extended psychoses were noted. When the drug was used for alleviation of anxiety and personality abnormalities, flashbacks and extended psychosis were reported.⁴⁵ It is suggested that these individuals had preexisting compensated psychological disturbances.^{3,79}

Flashbacks are reported in up to 15% to 80% of LSD users.⁵ Anesthesia, alcohol intake, and medication use may precipitate flashbacks.⁴⁸ These perceptions can be triggered during times of stress, illness, and exercise, and are often a virtual recurrence of the initial hallucinations. HPPD is a chronic disorder where flashbacks lead to impairment in social or occupational function. According to the Diagnostic and Statistical Manual V, the diagnosis of HPPD requires the recurrence of perceptual symptoms that were experienced while intoxicated with the hallucinogen that causes functional impairment and is not due to a medical condition.⁶ The etiology of HPPD is still unknown, and the reported incidence varies widely. Symptoms are primarily visual, and reality testing is typically intact in HPPD. Common perceptual and visual disturbances in HPPD include geometric forms, false and fleeting perceptions in the peripheral fields, flashes of color, intensified color, and halos around objects.⁷⁹ One finding described after LSD use is palinopsia, or “trailing,” which refers to the continued visual perception of an object after it has left the field of vision. These visual perceptions are associated with normal ophthalmologic examinations and abnormal EEG evaluations, suggesting a cortical etiology for the visual symptoms.

SUMMARY

- Hallucinogens are a diverse group of drugs that alter and distort perception, thought, and mood without clouding the sensorium.
- The lysergamide, phenylethylamine, and tryptamine hallucinogens share a serotonergic mechanism of action; however, other neurotransmitters may be responsible for the complex effects of these hallucinogens.
- Acute adverse psychiatric effects of hallucinogens include panic reactions, true hallucinations, psychosis, and major depressive dysphoric reactions.
- Hallucinogens rarely produce life-threatening problems, but can cause autonomic instability, seizures, and hyperthermia, particularly in large overdose.
- Meticulous supportive care with attention to abnormal vital signs and sedation with a benzodiazepine is often the only therapy required.

83 γ -HYDROXYBUTYRIC ACID (γ -HYDROXYBUTYRATE)

Brenna M. Farmer

HISTORY AND EPIDEMIOLOGY

GHB was discovered in 1960 while searching for an analog for γ -aminobutyric acid (GABA).³¹ Due to its central nervous system (CNS) depressive and amnestic properties, GHB was initially used as an anesthetic adjunct, especially in Europe but never gained favor in the United States for this indication. Outside the United States, GHB is still used for anesthesia or as an adjunct sedative for therapeutic hypothermia and wound care in children.^{43,44,53} During the 1970s, an investigational new drug protocol was submitted to the US Food and Drug Administration (FDA) to test the use of GHB as a treatment for sleep disturbances. In the 1980s and 1990s, body builders popularized GHB as an anabolic dietary supplement due to its release of growth hormone. Its euphoric effects were recognized at this time, and it rapidly gained favor as a “club drug.” Because it can cause coma and profound amnesia, GHB has been used in drug-facilitated sexual assault, and in 1990 the FDA banned all use of nonprescription GHB due to this concern.⁶¹

Following the FDA ban, the analogs GBL and 1,4-BD were quickly substituted for GHB in dietary supplements. After the Samantha Reid and Hillory J. Farias Date-Rape Prevention Act of 1999 was passed in 2000, the US Drug Enforcement Agency (DEA) classified GHB and its analogs as Schedule I substances claiming that GHB was a hazard to public safety.⁶⁸ Also in 2000, a new drug application was submitted to the FDA for GHB—under the generic name sodium oxybate and the trade name Xyrem—to reduce the incidence of cataplexy and improve the symptoms of daytime sleepiness in patients with narcolepsy.²⁹ This latter indication was approved in 2002 and given a Schedule III designation by the DEA,²⁹ which was expanded in 2005 to include the treatment of excessive daytime sleepiness in patients with narcolepsy. It is now also used “off-label” for fibromyalgia, chronic fatigue syndrome, and depressive disorders.^{6,56,65} However, in 2010, the FDA declined to approve GHB for fibromyalgia.

In 2007, during an epidemic of toxicity from toy beads, marketed under the names Bindeez or Aquadots, 1,4-BD was identified in the sticky surface material that allowed the beads to reversibly adhere to one another. Multiple cases of toxicity were reported, largely in England and Australia.^{25,55}

National statistics demonstrated a trend of escalating GHB abuse and poisoning throughout the 1990s. However, a decline has occurred in exposures reported to poison control centers and the Drug Abuse Warning Network in recent years. In 2002, there were 1386 exposures with GHB and its analogs and precursors reported to the American Association of Poison Control Centers (AAPCC)—Toxic Exposure Surveillance System, representing more than a twofold increase from approximately 600 GHB cases reported in 1996. Among these, 1181 exposures (85%) required treatment in a health care facility and resulted in 272 major outcomes and three deaths (Chap. 136).⁷⁴ From the 2011 AAPCC NPDS report, 464 cases mentioned exposure to GHB, its analogs, and precursors. In 303 of those cases, GHB, its analogs, and precursors were the single xenobiotic of exposure. Of the reported cases, 224 were treated in a health care facility and 144 of those cases had moderate or major outcomes.⁸ The Drug Abuse Warning Network’s 2010 estimates revealed 1787 emergency department visits for GHB exposures, similar to the number of visits from 2004 to 2009, with a range of 1036 to 2207 visits to the emergency department.⁶⁶ A recent retrospective review of deaths related to GHB, GBL, and 1,4-BD showed that men in their 20s were more likely to die from GHB poisoning. Thirty-four percent of these deaths were due to GHB alone.⁷⁸

The apparent trend of decreased GHB exposures in the United States after 2000 contrasts with the increased use reported in some European countries and Australia.^{12,15,30} In Melbourne, Australia, a retrospective study showed a 4%

increase per month in the number of ambulance calls related to GHB and its analogs from March 2001 to October 2005.¹² In Spain, a study of 505 consecutive GHB-poisoned patients presenting to one hospital, from 2001 to 2007, revealed that these patients come to the hospital on the weekends, in the early morning hours, and will likely require more treatment if ethanol, amphetamines or their derivatives, and/or cocaine are concomitantly used.²¹

PHARMACOLOGY

GHB is both a precursor and degradation product of GABA.⁶³ It has a dual pharmacologic profile, with the neuropharmacology of endogenous GHB being distinct and divergent from that of exogenously administered GHB. The principal difference is that the activity of endogenous GHB appears to be mediated by the GHB receptor, whereas the activity of exogenously administered GHB is most likely mediated by intrinsic activity at the GABA_B receptor.

Endogeneous GHB

GHB is formed from GABA by the enzymes GABA transaminase and succinic semialdehyde reductase³⁹ (Fig. 83–1). GHB is also endogenously transformed from GBL by lactonases and from 1,4-BD by alcohol and aldehyde dehydrogenases. Endogenous GHB acts as a putative neurotransmitter and is found in highest concentrations in the hippocampus, basal ganglia, hypothalamus, striatum, and substantia nigra.^{39,41,72} It has subcellular systems for synthesis, vesicular uptake, and storage in presynaptic terminals. It is released in a Ca²⁺-dependent manner following depolarization of neurons.

FIGURE 83–1. The synthesis and metabolism of γ -hydroxybutyric acid. ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase; SSA reductase = succinic semialdehyde reductase; SSAD = succinic semialdehyde dehydrogenase.

After release, GHB binds to GHB-specific receptors that modulate other neurotransmitter systems. Endogenous GHB acts predominantly on the GHB receptor, which is a G protein linked receptor located presynaptically.^{13,39,62} The GHB receptor is located in the synaptosomal membranes of neuronal cells most highly concentrated in the pons and hippocampus followed by the cerebral cortex and caudate. The GHB receptor has no affinity for typical GABA_A or GABA_B agonists such as GABA and baclofen, respectively. Localized application of GHB can produce a response that mimics the action of

endogenous GHB released by nerve stimulation.^{4,44} GHB receptors are highly associated with dopaminergic neurons and increase the concentration of dopamine by stimulating tyrosine hydroxylase to synthesize dopamine.^{39,64,69} GHB is also a neuromodulator of dopamine, acetylcholine, endogenous opioids, and glutamate.³⁹ It either increases (concentrations below 1 mM) or decreases (at higher concentrations) the release of dopamine throughout the mesolimbic system.¹¹ By contrast, GHB increases dopamine concentrations in the striatum and cortex in a dose-dependent manner by stimulating tyrosine hydroxylase to synthesize dopamine.^{39,40,64} GHB also increases the turnover of serotonin in the brain by stimulating both serotonin synthesis and breakdown.^{24,27} Furthermore, GHB decreases acetylcholine in the brainstem and corpus striatum, as well as in the hippocampus (via GABA_B receptors).^{45,64} GBL, but not GHB itself, increases total brain acetylcholine concentrations by decreasing firing of cholinergic neurons.^{23,32,58}

Through an unclear mechanism, GHB increases the release of growth hormone by promoting slow wave sleep without effecting total sleep time and GHB release is enhanced.^{71,73} Although GHB has no effect on total sleep time, it decreases latency to slow wave sleep while also decreasing the time spent in stages 1 and 2 of the sleep cycle.³³ GHB activity is terminated by active uptake from the synaptic cleft for metabolism by specific cytosolic and mitochondrial enzymes.

Exogenous GHB

Exogenous GHB, which produces supraphysiologic GHB concentrations, acts predominantly on the GABA_B receptor, which is found throughout the cerebral cortex, cerebellum, and thalamus.^{22,54,75} Presynaptically and postsynaptically, these receptors signal the adenylate cyclase system to activate calcium channels and G protein–coupled inwardly rectifying K⁺ channels.⁵ Through these GABA_B receptor signaling pathways, both dopamine and acetylcholine pathways are altered leading to decreased dopamine release and decreased acetylcholine concentrations.^{11,45} These effects of GHB are potentiated by baclofen, a GABA_B receptor agonist. Further discussion of these receptors and pathways is found in Chap. 14.

GHB ANALOGS

GBL, like GHB, exists in the mammalian brain.¹⁴ Its pharmacologic properties are only evident after conversion to its active metabolite, GHB. Like GBL, 1,4-BD occurs naturally in the brain and exerts its pharmacologic and toxicologic properties only when converted to GHB by alcohol dehydrogenase.⁵¹

Table 83–1 lists other GHB analogs known to result in similar toxicity and lists synonyms for GHB, GBL, and 1,4-BD that are often found on the labels of commercial and illicit products.

TABLE 83–1. Common Synonyms for GHB and Analogs					
GHB	GBL	1,4-BD	GHV	GVL	THF
γ-Hydroxybutyrate	γ-Butyrolactone	1,4-Butanediol	γ-Hydroxyvaleric Acid	γ-Valerolactone	Tetrahydrofuran
γ-Hydroxybutyric acid	2(3H)-Furanone dihydro	1,4-Butylene glycol	γ-Methyl-GHB	4-Hydroxypentanoic acid lactone	No other synonyms
4-Hydroxybutyric acid	Butyrolactone	1,4-Dihydroxybutane		4,5-Dihydro-5-methyl-2(3H)-furanone	
sodium salt	4-Butyrolactone	1,4-Tetramethylene glycol		γ-Methyl-GHB	
γ-Hydroxybutyric acid	Dihydro-2(3H)-Furanone				
Sodium salt	2(3H)-Furanone				
Sodium oxybate	Tetrahydro-2-furanone				
Sodium 4-hydroxybutyrate	4-Deoxtetronic acid				
4-Hydroxybutanoic acid	Butyryl lactone				
	Butyric acid lactone				
	Butyrolactone-γ				
	4-Hydroxybutyric acid lactone				
	γ-Hydroxybutyric acid lactone				
	4-Butanolide				
	1,4-Butanolide				
	1,4-Lactone				

PHARMACOKINETICS AND TOXICOKINETICS

The endogenous production and metabolism of GHB are both shown in Fig. 83–1. Exogenous GHB is typically ingested in its sodium salt form. Oral bioavailability of exogenous GHB is approximately 60% in rats.^{34,35} It is rapidly absorbed from the gastrointestinal tract in 15 to 45 minutes and displays two-compartment distribution in animals with an initial volume of distribution of 0.4 L/kg and final volume of distribution 0.6 L/kg.^{16,34–36} It is lipid soluble and crosses the blood–brain barrier rapidly. It does not bind significantly to any plasma proteins.⁴⁷ GHB is metabolized mainly by succinic semialdehyde reductase (also known as GHB dehydrogenase) to succinic semialdehyde, which is subsequently metabolized to succinate and enters the Krebs cycle (Fig. 83–1). GHB is also metabolized directly to succinate via β oxidation in the liver.⁴⁹ GHB is subject to first-pass metabolism by the cytochrome P450 system; however, the specific isozyme is not known.³⁴ In adult volunteers, the elimination half-life is 20 to 53 minutes. Less than 5% of GHB is excreted unchanged in the urine.⁴⁷

GBL undergoes conversion to GHB by a lactonase.^{51,52} In comparison with GHB, GBL is more rapidly absorbed from the gastrointestinal tract and has a longer duration of action, both of which result from higher lipid solubility. 1,4-BD exerts its effects after conversion to GHB by alcohol dehydrogenase (ADH).^{9,50} Therefore, coingestion with ethanol can prolong the onset of clinical effects because of competitive inhibition of ADH.^{46,57}

In patients with HIV taking protease inhibitors, GHB first-pass metabolism is altered such that low doses of GHB can produce toxic manifestations. This results from the interactions of the protease inhibitors on the cytochrome P450 system.^{1,26}

CLINICAL MANIFESTATIONS

The clinical manifestations of GHB are mainly due to its effects on the CNS. Initial clinical effects of ingested GHB occur in 15 to 20 minutes and peak in 30 to 60 minutes.⁷ The clinical manifestations of GHB follow a steep dose–response curve. Doses of 20 to 30 mg/kg create euphoria, memory loss, and drowsiness, while doses of 40 to 60 mg/kg result in coma.^{19,41} Doses of 25 mg/kg given to naïve healthy volunteers result in mean serum GHB concentrations of 39.4 ± 25.2 $\mu\text{g/mL}$ (range, 4.7–76.3 $\mu\text{g/mL}$).⁷ Vital sign changes include bradycardia, hypotension, bradypnea, and hypothermia. Pupils may be miotic and poorly responsive to light. Acute toxicity typically results in CNS depression/coma, respiratory depression, salivation, vomiting, and sometimes myoclonus.^{16,38} Of these findings, the most concerning is respiratory depression, as apnea and death may ensue.^{10,37,77} Salivation and vomiting can complicate the respiratory depression leading to pulmonary aspiration in patients with a depressed level of consciousness. Case series also report aggressive and combative behavior, which may be exacerbated when assessing the airway and initiating endotracheal intubation in those patients with compromised consciousness.^{16,76} Motor manifestations can be confusing. Although GHB induces seizures (EEG changes and convulsions) in animal models, this has never been demonstrated in humans. More commonly, in humans GHB induces myoclonus that can be confused with seizures.¹⁸

Other findings reported in patients taking prescribed therapeutic doses for narcolepsy include confusion, abnormal thought processes, and depression.²⁹ The most common adverse effects reported in these patients using prescribed GHB include nausea, dizziness, headache, vomiting, and urinary incontinence.²⁹

Recovery from overdose occurs rapidly, typically in less than 6 to 8 hours, and patients often extubate themselves following rapid improvement of their level of consciousness. No sequelae should be expected if hypoxia or aspiration did not occur.

Frequent GHB users can develop both tolerance and dependence to GHB.^{20,61} Such patients typically use GHB or one of its analogs every 2 to 4 hours over a prolonged period of time, with cumulative daily doses in the range of 10 g or more.⁴² In rats receiving doses of GHB every 3 hours for up to 6 days tolerance was observed.² In patients with dependence, withdrawal symptoms can occur.

DIAGNOSTIC TESTING

Routine “screens” for drugs of abuse do not typically include analysis for GHB. Specific testing for GHB and its related analogs usually is not requested unless there is suspicion of its use associated with drug-facilitated sexual assault. However, urine and serum testing can also be performed if needed for forensic purposes. Gas chromatography–mass spectrometry is the test of choice for both urine and serum. GHB can be detected in the urine up to 12 hours after use.⁷ Interpretation of these tests must include cutoff concentrations as GHB, GBL, and 1,4-BD also occur naturally. These cutoff concentrations must be able to distinguish endogenous production and therapeutic use (as in patients using prescribed GHB for narcolepsy) from abuse or misuse. However, attempts to correlate concentrations with clinical effects in any individual may not be valid when used chronically and when tolerance develops. Due to rapid metabolism and elimination,

concentrations return to baseline shortly after drug naïve patients become clinically normal. Urinary concentrations of endogenous GHB are usually less than 5 to 10 µg/mL, while serum concentrations of endogenous GHB are usually less than 5 µg/mL.⁷ In patients receiving a 25 mg/kg dose of GHB, serum GHB concentrations ranged from 4.7 to 76.3 µg/mL 20 to 45 minutes after administration and urine concentrations from below the detection limit to 840 µg/mL. In general, loss of consciousness occurs when serum concentrations reach 50 µg/mL, and deep coma occurs when concentrations rise above 260 µg/mL.⁵⁹

Screening for GHB may also routinely be performed when specific genetic or metabolic disorders are of concern. In particular, elevated GHB concentrations on a urinary organic acid screen in a child may indicate a succinic semialdehyde dehydrogenase deficiency. These children have developmental delay, seizures, hypotonia, and elevated GHB concentrations in the blood, urine, and cerebrospinal fluid.⁴⁸ One case report describes a child with a serum GHB concentration of 775 µg/mL, significantly higher than most patients with exogenous GHB poisoning.²⁸

Other routine tests in patients with depressed levels of consciousness include a rapid evaluation of blood glucose, an ethanol concentration as clinically indicated, and electrocardiography. Electrocardiographic findings may include sinus bradycardia and prominent U waves, which may be related to the sinus bradycardia. Other standard laboratory tests are typically normal.¹⁰ When intentional overdose or self-harm is suspected, a determination of serum acetaminophen concentration is also indicated. Other studies should be obtained based on the clinical condition of the patient.

MANAGEMENT

Supportive care is the mainstay of therapy for patients with GHB toxicity. All patients presenting to the hospital should have their airway, breathing, and circulation assessed immediately. Patients with GHB toxicity may require airway protection in the presence of profound coma and respiratory depression or apnea. However, many become combative during the intubation process. Supportive care with a nasal airway may suffice in the snoring patient who has an appropriate gag and respiratory function. The need for endotracheal intubation is a bedside clinical decision and should be based on the ability of the patient to oxygenate and ventilate, especially when the diagnosis is known or highly suspected as recovery is expected shortly. Atropine may be given as needed for severe bradycardia. However, in most instances, the bradycardia will not necessitate treatment in otherwise healthy patients. An intravenous catheter should be established and intravenous fluids infused as necessary for hypotension. Patients should be warmed if they are hypothermic.

There is no role for gastric decontamination in patients with GHB toxicity as GHB is rapidly absorbed from the gastrointestinal tract. The increased risk of vomiting and aspiration also limits any beneficial role of gastric decontamination. If a coingestant is present, then appropriate decontamination methods may be employed if there are no contraindications to their use.

Other therapies such as dextrose and thiamine should be administered as clinically indicated. Some proposed antidotes include physostigmine, naloxone, and flumazenil. All these antidotes lack a pharmacologic basis for use and may place the patient at increased risk as other drugs of abuse commonly used with GHB may interact with these xenobiotics. An animal model did not support the use of physostigmine in GHB toxicity,³ nor did a systematic literature review.⁷⁰ Naloxone can be administered to the patient with respiratory and CNS depression in the setting of unknown or presumed overdose. In GHB toxic patients, naloxone administration is largely unsuccessful at improving clinical status.³⁷

Those patients whose symptoms resolve may be discharged from the hospital following appropriate psychosocial evaluation for abuse and dependency. All patients who do not follow the expected course of resolution of their clinical manifestations (approximately 6 hours) should be admitted to the hospital and investigated for other potential etiologies.

GHB WITHDRAWAL

Patients who use GHB or its analogs daily in large quantities can develop tolerance and dependence.²⁰ Such patients are prone to withdrawal if they abruptly cease or decrease their daily dose. In patients prescribed GHB for narcolepsy, withdrawal rarely develops when the GHB is used as prescribed as the recommended doses are low and given only at night.^{29,67} Most patients with GHB withdrawal are body builders.

GHB withdrawal is similar to ethanol and benzodiazepine withdrawal ([Chap. 15](#)). It can be severe and potentially life threatening. The onset of withdrawal typically occurs 1 to 6 hours after last use. Men appear to be more commonly affected than women.⁴² Manifestations of withdrawal include tachycardia, hypertension, tremors, agitation, dysphoria, nausea, vomiting, auditory and visual hallucinations, and seizures.^{17,20,42,67}

For acute withdrawal symptoms, benzodiazepines and supportive care are the mainstays of therapy.^{42,67} Rapid cooling, intravenous fluids, and evaluation for other medical or traumatic illnesses should be performed. These patients may require large doses of benzodiazepines to control symptoms. In patients with withdrawal symptoms refractory to benzodiazepines, barbiturates and propofol can be considered.^{42,60,67} Baclofen, a GABA_B receptor agonist, is also a reasonable

consideration in severe GHB withdrawal, although research must be done to determine appropriate dosing and escalation of dosing. In these refractory patients, endotracheal intubation may be required ([Chap. 15](#)).

SUMMARY

- GHB is a unique xenobiotic because it occurs naturally as an endogenous neurotransmitter, it is a licensed pharmaceutical, and it is a drug of abuse.
- GHB, GBL, and 1,4-BD result in GHB toxicity through complex neuropharmacologic effects to rapidly produce CNS and respiratory depression that is characteristically of short duration.
- GHB toxicity rarely results in death when patients are treated with supportive care.
- A life threatening withdrawal syndrome can occur with cessation or decreased use of the drug and its related analogs. This withdrawal syndrome should be treated in a manner similar to ethanol withdrawal or sedative-hypnotic withdrawal.
- With appropriate care of both acute intoxication and withdrawal, patients can recover without sequelae, but psychosocial care and referral for management of abuse or dependency are essential.

84 INHALANTS

Heather Long

HISTORY AND EPIDEMIOLOGY

Inhalant abuse is defined as the deliberate inhalation of vapors for the purpose of changing consciousness or becoming “high.” It is also referred to as volatile substance abuse and was first described in medical literature in 1951.³⁷ Inhalants are appealing to adolescents because they are inexpensive, readily available, and sold legally. Initially, inhalant abuse was viewed as physically harmless, but reports of “sudden sniffing death” began to appear in the 1960s.¹¹ Shortly thereafter, evidence surfaced of other significant morbidities, including organic brain syndromes, peripheral neuropathy, and withdrawal.

The demographics of inhalant abuse differ markedly from those of other traditional substances of abuse. According to the 2011 National Survey on Drug Use and Health, inhalants continued to be the most frequently reported illicit xenobiotics used by 12 and 13 year-olds. The age at initiation of illicit drug use is youngest for those choosing inhalants, and the reported usage of inhalants peaked at age 14.¹⁴⁰ A worrisome trend reported by the 2011 Monitoring the Future study is that although the perceived risk of even one-time use of an inhalant has fallen steadily since 2001, and a study of 279 youths who were lifetime inhalant users found 37% perceived experimental inhalant use of slight or no risk.^{100,116}

In the United States, the problem is greatest among children of lower socioeconomic groups. Non-Hispanic white adolescents are the most likely and black adolescents the least likely to use inhalants.^{14,96} Although inhalant use is a problem in both urban and rural communities, it is more prevalent in rural settings.^{96,134} This may relate to the easier access that teens in urban areas have to other drugs of abuse.

Inhalant abuse includes the practices of sniffing, huffing, and bagging. Sniffing entails the inhalation of a volatile substance directly from a container, as occurs with modeling glue or rubber cement. Huffing involves pouring a volatile liquid onto fabric, such as a rag or sock, and placing it over the mouth, nose, or both while inhaling and is the method used by more than 60% of volatile-substance abusers.⁹⁶ Bagging refers to instilling a solvent into a plastic or paper bag and rebreathing from the bag several times; spray paint is among the xenobiotics commonly used with this method.

XENOBIOTICS COMMONLY USED

There are myriad xenobiotics abused as inhalants (Table 84–1), most of which are volatile hydrocarbons. Hydrocarbons are organic compounds comprised of carbon and hydrogen atoms and are divided into two basic categories: aliphatic (straight, branched, or cyclic chains) and aromatic. Most of the commercially available hydrocarbon products are mixtures of hydrocarbons; for example, gasoline is a mixture of aliphatic and aromatic hydrocarbons that may consist of more than 1500 compounds. Substituted hydrocarbons contain halogens or other functional groups such as hydroxyl or nitrite that are substituted for hydrogen atoms in the parent structure. Solvents are themselves a heterogeneous group of xenobiotics that are used to dissolve other chemical compounds or provide a vehicle for their delivery.

TABLE 84–1. Common Inhalants and the Constituent Xenobiotics

<i>Inhalant</i>	<i>Chemical</i>
Glues/adhesives	Toluene, <i>n</i> -hexane, benzene, xylene, trichloroethane, trichloroethylene, tetrachloroethylene, ethyl acetate, methylethyl ketone, methyl chloride
Spray paint	Toluene, butane, propane
Computer keyboard duster	Difluoroethane, tetrafluoroethane
Hair spray, deodorants, air fresheners	Butane, propane, fluorocarbons
Cigarette lighter fluid	Butane
Paint thinner	Toluene, methylene chloride, methanol
Gasoline	Aliphatic and aromatic hydrocarbons
Carburetor cleaner	Methanol, methylene chloride, toluene, propane
Dry cleaning agents, spot removers, degreasing agents	Tetrachloroethylene, trichloroethane, trichloroethylene
Typewriter correction fluid	Trichloroethane, trichloroethylene
Nail polish remover	Acetone
Paints, lacquers, varnishes	Trichloroethylene, toluene, <i>n</i> -hexane
"Poppers"	Amyl nitrite, isobutyl nitrite
Room deodorizers	Butyl nitrite, isobutyl nitrite, cyclohexyl nitrite
Whipped cream dispensers, "whippits"	Nitrous oxide

The most commonly inhaled volatile hydrocarbons are fuels, such as gasoline, and solvents, such as toluene.¹³⁴ Other commonly inhaled hydrocarbon-containing products include spray paints, lighter fluid, air fresheners, and glue. In most reported cases of inhalant use, the inhalant is identified not by its chemical name (eg, butane and toluene) but rather by its intended use (eg, lighter fluid and paint thinner). Because exact components may vary between products, identification by the intended commercial use of the product is inaccurate and imprecise. The choice of xenobiotic used likely reflects their availability: cases from the 1970s frequently reported abuse of antiperspirants and typewriter correction fluid; computer and electronics cleaners have replaced these products. Dusting refers to the inhalation of compressed air cleaners containing halogenated hydrocarbons (eg, CRC Dust Off), marketed for cleaning computer keyboards and electronics equipment. Reports of exposures to these products, including death and ventricular dysrhythmias, doubled in 2005 and tripled in 2006.⁹⁵ Of the 30 deaths attributed to recreational inhalant use in North Carolina between 2000 and 2008, one-third involved compressed-air products; yet, dusting is not perceived to be harmful by users and, surprisingly, many users do not consider it a form of inhalant abuse.^{64,95}

Although volatile alkyl nitrites are technically substituted hydrocarbons, they have pharmacologic and behavioral effects, as well as patterns of abuse, distinct from the other volatile hydrocarbons. For this reason, researchers usually classify them as a separate category among abused inhalants. Amyl nitrite is the prototypical volatile alkyl nitrite.⁹ Amyl nitrite became popular in the 1960s with the appearance of "poppers," small glass capsules containing the chemical in a plastic sheath or gauze. When crushed, the ampules release the amyl nitrite. When nonprescription sales of amyl nitrite were restricted in 1968, sex and drug paraphernalia shops began selling small vials of butyl and isobutyl nitrites marketed as room deodorizers or liquid incense.^{9,91} Because of further restrictions on sales of alkyl nitrites, most of these products now contain chemicals not technically alkyl nitrites, such as cyclohexyl nitrite.⁹

The most commonly used non-hydrocarbon inhalant is nitrous oxide. Nitrous oxide, or "laughing gas," is used medically as an inhalational anesthetic (Chap. 68). It is the propellant in supermarket-bought whipped cream canisters, and cartridges of the compressed gas are sold for home use in whipped cream dispensers. These battery-sized metal containers of compressed gas may be used as "whippits," in which the container is punctured using a device known as a "cracker," and the escaping gas is either inhaled directly or collected in a balloon and then rebreathed.

PHARMACOLOGY

Although chemically heterogeneous, inhalants are generally highly lipophilic and gain rapid entrance into the central nervous system (CNS). Little is known about the cellular basis of the effects of inhalants. Evidence to date shows that the most commonly abused hydrocarbons have molecular mechanisms similar to those of other classic CNS depressants, frequently with common cellular sites of action. Their effects are probably best represented by the model for ethanol in which multiple different cellular mechanisms explain diverse pharmacologic and toxicologic effects.⁹

Volatile Hydrocarbons

The clinical effects of the volatile hydrocarbons are likely mediated through stimulation of inhibitory neurotransmission and antagonism of excitatory neurotransmission within the CNS. Like ethanol, toluene, trichloroethane (TCE), and trichloroethylene enhance γ -aminobutyric acid type A (GABA_A) receptor-mediated synaptic currents as well as glycine-receptor-activated ion function. Stimulation of these receptors acts to increase chloride permeability, hyperpolarizing the neuronal cell membrane and inhibiting excitability.^{16,70,136} Like inhaled anesthetics, these abused inhalants appear to act presynaptically on the GABA_A nerve terminals. Toluene-induced increase in inhibitory synaptic current is blocked by dantrolene and ryanodine, suggesting toluene effects release of calcium from intracellular nerve terminal stores.⁹⁰ Despite very different molecular structures, ethanol, enflurane, chloroform, toluene, and TCE compete for binding sites at α_1 glycine receptors.¹⁵ Like ethanol and subanesthetic concentrations of isoflurane, toluene, TCE, and benzene all interfere with glutamate-mediated excitatory neurotransmission by inhibiting N-methyl-D-aspartate (NMDA) receptor-mediated currents in a concentration dependent manner.^{8,39,118,129} Furthermore, repeated toluene exposure increases NMDA receptors, suggesting that chronic exposure can lead to upregulation of excitatory neurotransmission as occurs with ethanol.^{8,157}

Toluene is the prototypical volatile hydrocarbon and the best studied. In animal models, differences in pharmacologic action are demonstrated between toluene and other alkylbenzenes, and halogenated hydrocarbons such as TCE, and acetone.^{22,39,85,130,144} These differences may represent evidence that specific cellular sites for their actions exist. In addition, these differences may explain the variation in their abuse potential or their clinical effects.^{9,85} Despite these distinctions, there are marked similarities in the behavioral and pharmacologic effects of the volatile hydrocarbons. Moreover, the clinical effect profile shared by the volatile hydrocarbons, subanesthetic concentrations of general anesthetics, ethanol, and benzodiazepines suggests that they share cellular mechanisms. Shared clinical effects include anxiolysis,²⁷ anticonvulsant effects,¹⁵⁹ impaired motor coordination,¹⁰³ and evidence of physical dependence on withdrawal.^{47,48}

Most research on inhalants has focused on the neural basis of their effects, yet it is the cardiotoxicity that is responsible for the majority of their lethal effects. In vivo, toluene reversibly inhibits myocardial voltage-activated sodium channels.⁴⁰ Similarly, it inhibits muscle sodium channels but with less potency.⁵⁵ Ethanol and toluene have opposite effects on potassium channels in vivo; ethanol potentiates the large conductance, calcium-activated potassium channels as well as certain G protein-coupled inwardly rectifying potassium channels, while toluene inhibits them.⁴² The combined inhibition of the sodium channels and the inwardly rectifying potassium channels is postulated to play a role in cardiac dysrhythmias and sudden sniffing death associated with the aromatic and halogenated hydrocarbons. Animal studies show toluene and 1,1,1-trichloroethane produce biphasic dose-response curves for motor activity: low concentrations yield motor excitation, while high concentrations produce sedation, motor impairment, and anesthesia.^{23,152} Molecular mechanisms underlying both the neural and cardiac effects may maximize the risk effects and explain the observed clinical phenomenon described in sudden sniffing deaths (see below).

Scant data exist on the pharmacokinetics of the inhalants. Most data are derived from studies on occupational and environmental exposures and have limited applicability to intentional inhalation. More relevant to the understanding of inhalants are the similarities with the inhalational anesthetics, many of which are also halogenated hydrocarbons. Factors determining pharmacokinetic and pharmacodynamic effects of a given inhalational anesthetic include its concentration in inspired air; partition coefficient; interaction with other inhaled substances, ethanol, and drugs; the patient's respiratory rate and blood flow; percent body fat; and individual variation in drug metabolism (Chap. 68).⁵⁹

Partition coefficients measure the relative affinity of a gas for two different substances at equilibrium and are used to predict the rate and extent of uptake of an inhaled substance. The blood:gas partition coefficient is most commonly referenced. The higher the number, the more soluble the substance is in blood. Substances with a low blood:gas partition coefficient, like nitrous oxide, are rapidly taken up by the brain and, conversely, are rapidly eliminated from the brain once exposure is ended (Table 84-2).

TABLE 84-2. Blood:Gas Partition Coefficients, Routes of Elimination, and Important Metabolites of Selected Inhalants

<i>Xenobiotic</i>	<i>Blood:Gas Partition Coefficient (98.6°F (37°C))</i>	<i>Routes of Elimination</i>	<i>Important Metabolites</i>
Acetone	243–300	Largely unchanged via exhalation 95% and urine 5%	None
n-Butane	0.019	Largely unchanged via exhalation	None
Carbon tetrachloride	1.6	50% unchanged via exhalation; 50% hepatic metabolism and urinary excretion	CYP2E1 to trichloromethyl radical, trichloromethyl peroxy radical, phosgene
n-Hexane	2	10%–20% exhaled unchanged; hepatic metabolism and urinary excretion	CYP2E1 to 2-hexanol, 2,5-hexanedione, γ -valerolactone
Methylene chloride	5–10	92% exhaled unchanged; hepatic metabolism and urinary excretion	1. CYP2E1 to CO and CO ₂ 2. Glutathione transferase to CO ₂ , formaldehyde, and formic acid
Nitrous oxide	0.47	> 99% exhaled unchanged	None
Toluene	8–16	< 20% exhaled unchanged; > 80% hepatic metabolism and urinary excretion	CYP2E1 to benzoic acid, then 1. Glycine conjugation to form hippuric acid (68%) 2. Glucuronic acid conjugation to benzoyl glucuronide (insignificant pathway except following large exposure)
1,1,1-Trichloroethane	1–3	91% exhaled unchanged; hepatic metabolism and urinary excretion	CYP2E1 to trichloroethanol, then 1. Conjugated with glucuronic acid (urochloralic acid) or 2. Further oxidized to trichloroacetic acid
Trichloroethylene	9	16% exhaled unchanged; 84% hepatic metabolism and urinary excretion	CYP2E1 to epoxide intermediate (transient); chloral hydrate (transient); trichloroethanol (45%), trichloroacetic acid (32%). Urinary trichloroacetic acid peaks 2–3 days postexposure
1,2-Dichloro-1,1-difluoroethane	NA	NA	CYP2E1 to 2-chloro-2,2-difluoroethyl glucuronide, 2-chloro-2,2-difluoroethyl sulfate, chlorodifluoroacetic acid, chlorodifluoroacetaldehyde hydrate, chlorodifluoroacetaldehyde-urea adduct, and inorganic fluoride. No covalently bound metabolites to liver proteins.

In a rodent model of inhalation abuse of toluene and acetone, the rapidity of onset and the extent of CNS depression were dependent on the concentration of the solvent inhaled.³⁰ There was a parallel relationship between brain concentration and pharmacologic effect during induction (inhalation) and postexposure. Brain and liver concentrations dropped rapidly after exposure; concentration in blood decreased at the slowest rate. Elimination was biphasic: rapid elimination during the first step was a result of tissue redistribution, alveolar ventilation, and metabolic clearance. During the second phase, there was a slow decrease in tissue concentrations as a result of the gradual mobilization from adipose tissue with subsequent exhalation or metabolism. Acetone, which is more water soluble than toluene, is less potent and slower acting than toluene, but is eliminated much more slowly than toluene and has a much longer duration of action.³⁰ Positron emission tomography (PET) studies using (¹¹C) radiolabeled toluene, butane, and acetone in nonhuman primates showed rapid uptake of radioactivity in striatal and frontal regions of the cortex followed by rapid clearance from the brain.⁵⁶ Whole-body PET scans in mice showed excretion through the kidneys and liver.⁵⁷

The inhalants are eliminated unchanged by the lungs, they undergo hepatic metabolism, or both (Table 84–2). For some, the percentage that is metabolized versus eliminated unchanged varies with the exposure dose. Nitrous oxide and the aliphatic hydrocarbons are frequently eliminated unchanged in the expired air. The aromatic and halogenated hydrocarbons are metabolized extensively via the cytochrome P450 (CYP) system, particularly CYP2E1, which has a substrate spectrum that includes a number of aliphatic, aromatic, and halogenated hydrocarbons.^{20,65,66,160} Extrahepatic expression of CYP2E1 occurs to a lesser extent but may be of toxicologic significance, particularly in the kidneys and the dopaminergic cells of the substantia nigra.^{21,71,148} In humans, there appears to be no significant gender difference in CYP2E1 activity; however, it is polymorphic and, as such, allelic distributions vary among different human populations.^{21,132} Moreover, this polymorphism may explain the varying degrees of toxicity exhibited following inhalant abuse.

Reward and reinforcement effects of inhalants are readily demonstrated. While the mechanisms underlying their reinforcement behavior remain poorly studied, activation of the mesolimbic dopamine system is thought to play an important role in solvent abuse, similar to more commonly studied drugs of abuse.^{57,121} Interestingly, the reward and

reinforcement effects of toluene appear to vary with age of exposure, suggesting that physiologic as well as psychosocial factors play a role in the prevalence of inhalant abuse among adolescents compared with adults.^{12,25,109} Furthermore, age at exposure differentially affects dendritic growth in the brain suggesting that the adolescent brain is more at risk for cognitive impairment following inhalant use.¹¹¹

Volatile Alkyl Nitrites

Unlike other volatile hydrocarbons, the volatile alkyl nitrites do not have any demonstrable direct effects on the CNS. Their effects are mediated through smooth muscle relaxation in the central and peripheral vasculature, and they share a common cellular pathway with other nitric oxide (NO) donors similar to nitroglycerin and sodium nitroprusside.⁷⁹ A rat model of inhalation of isobutyl nitrite found a half-life of 1.4 minutes with almost 100% biotransformation to isobutyl alcohol. Bioavailability following inhalation was estimated to be 43%.⁷⁸

Nitrous Oxide

The pharmacokinetics and pharmacodynamics of nitrous oxide (N₂O) abuse are derived from its use as an inhalational anesthetic. Anesthetic uptake or induction, as well as emergence with N₂O, is rapid because of its low solubility in blood, muscle, and fat.¹³⁷ No appreciable metabolism of N₂O is present in human tissue. An animal study found N₂O significantly inhibited excitatory NMDA-activated currents and had no effect on GABA-activated currents.⁷² N₂O also stimulates dopaminergic neurons, but the significance of this in mediating its anesthetic effects remains unclear.^{76,104}

Animal studies suggest the analgesic effects (or more accurately the antinociceptive effects because it refers to animals) of N₂O appear to be mediated through opioid peptide release in the midbrain. These antinociceptive effects can be reversed by the opioid antagonist naloxone.¹⁸ However, in humans the anesthetic effects are not attenuated by naloxone, and the subjective and psychomotor effects of N₂O are not extinguished by even high doses of naloxone.^{133,161}

CLINICAL MANIFESTATIONS

Signs and symptoms of inhalant use may be subtle, tend to vary widely among individuals, and generally resolve within several hours of exposure. Following acute exposure, there may be a distinct odor of the abused inhalant on the patient's breath or clothing. Depending on the inhalant used and the method, there may be discoloration of skin around the nose and mouth. Mucous membrane irritation may cause sneezing, coughing, and tearing. Patients may complain of dyspnea and palpitations. Gastrointestinal complaints include nausea, vomiting, and abdominal pain. After an initial period of euphoria, patients may have residual headache and dizziness.

Volatile Hydrocarbons

The CNS is the intended target of the inhalants and is most susceptible to its adverse effects. Initial CNS effects include euphoria and hallucinations, both visual and auditory, as well as headache and dizziness. As toxicity progresses, CNS depression worsens and patients may develop slurred speech, confusion, tremor, and weakness. Transient cranial nerve palsies are reported.¹⁴² Further CNS depression is marked by ataxia, lethargy, seizures, coma, and respiratory depression. These acute encephalopathic effects generally resolve spontaneously and associated neuroimaging abnormalities are not reported.⁵⁰

As can be expected, given the high lipophilicity of most inhalants, toxicity from chronic use is manifested most strikingly in the CNS. Toluene leukoencephalopathy, characterized by dementia, ataxia, eye movement disorders, and anosmia, is the prototypical manifestation of chronic inhalant neurotoxicity. Patients with toluene leukoencephalopathy display characteristic neurobehavioral deficits reflecting white matter involvement, including inattention, apathy, impaired memory, and visuospatial skills, with relative preservation of language.⁵⁰ Autopsy studies reveal white-matter degeneration including cerebral and cerebellar atrophy and thinning of the corpus callosum.^{2,80,122} On microscopy, there is diffuse demyelination with relative sparing of the axons. Abundant perivascular macrophages containing coarse or laminar myelin debris found in areas of the greatest myelin loss is a characteristic pathologic feature.^{2,50} This targeting of myelin, which is 70% lipid, may be explained by the lipophilicity of toluene.⁵⁰ As myelination continues at least through the second decade of life, the typical toluene abuser who begins inhaling during adolescence may be particularly susceptible to its toxic CNS effects.⁴⁹ Advances in magnetic resonance imaging (MRI) with gadolinium, which allow enhanced visualization of the cerebral white matter, demonstrate that the extent of white matter injury in the brain directly corresponds to the clinical severity of toluene leukoencephalopathy.⁵⁰ It is postulated that reactive oxygen species generated either by toluene or its metabolite benzaldehyde induce lipid peroxidation in the brain.^{93,120} Genetic polymorphisms and host susceptibility among chronic abusers are also hypothesized to play a role.⁶¹

Acute cardiotoxicity associated with hydrocarbon inhalation is manifested most dramatically in “sudden sniffing death.” In witnessed cases, sudden death frequently occurred when sniffing was followed by some physical activity. Examples include running or wrestling or a stressful situation like being caught sniffing by parents or police.¹¹ It is thought that the inhalant “sensitizes the myocardium” by blocking the potassium current (I_{KR}), thereby prolonging repolarization.¹⁰⁶ This produces a substrate for dysrhythmia propagation; the activity or stress then causes a catecholamine surge that initiates the dysrhythmia (Chap. 16).¹⁰⁶ Cardiac dysrhythmias following the inhalation of hydrocarbons were documented with the halogenated inhalational anesthetics in the early 1900s, and this association was subsequently confirmed in both animal and human studies.^{51,143}

More typically, the clinical presentation of a patient with hydrocarbon cardiotoxicity may include palpitations, shortness of breath, syncope, and abnormalities on electrocardiography, including atrial fibrillation, premature ventricular contractions, QT interval prolongation, and U waves.

Multiple case reports of ventricular fibrillation follow intentional inhalation of other hydrocarbons such as butane fuel,^{63,156} fluorinated hydrocarbons, and Glade Air Freshener (SC Johnson), which contains a mixture of short-chain aliphatic hydrocarbons.⁸⁷ Among 44 patients with a history of inhalant abuse, specifically toluene exposure, the QT interval and corrected QT dispersion were significantly greater than in healthy controls. Furthermore, the QT interval and corrected QT dispersion were significantly greater in the 20 toluene abusers with a history of unexplained syncope than in asymptomatic abusers and controls.³ Although cardiotoxic effects of inhalant abuse are generally acute, dilated cardiomyopathy is reported with chronic abuse of toluene and trichloroethylene.^{97,158} Microscopy reveals evidence of chronic myocarditis with fibrosis.¹⁵⁸

The most significant respiratory complication of inhalational abuse is hypoxia, which is either caused by displacement of inspired oxygen with the inhalant, reducing the fraction of inspired oxygen (FiO_2), or by rebreathing of exhaled air, as occurs with bagging. Direct pulmonary toxicity associated with inhalants is most often a result of inadvertent aspiration of a liquid hydrocarbon (Chap. 108). Aspiration injury is associated with the acute respiratory distress syndrome, a continuum of lung injury characterized by increased permeability of the alveolar–capillary barrier and the resulting influx of edema into the alveoli, neutrophilic inflammation, and an imbalance of cytokines and other inflammatory mediators.¹⁵¹ Reports of asphyxiation initially ascribed to inhalant abuse were later found caused by suffocation by a plastic bag, mask, or container pressed firmly to the face, and not specifically by toxicity of the inhaled vapor.^{11,34,150}

Irritant effects on the respiratory system are frequently transient, but patients may develop chemical pneumonitis. This syndrome is characterized by tachypnea, fever, tachycardia, crackles, rhonchi, leukocytosis, and radiographic abnormalities, including perihilar densities, bronchovascular markings, increased interstitial markings, infiltrates, and consolidation. Acute eosinophilic pneumonia following abuse of a fabric protector containing 1,1,1-trichloroethane is also reported.⁷⁷ Barotrauma, from deep inhalation or breath holding, presents as pneumothorax, pneumomediastinum, or subcutaneous emphysema.¹²⁵

Hepatotoxicity is associated with exposure to halogenated hydrocarbons, particularly carbon tetrachloride (CCl_4), as well as chloroform, trichloroethane, trichloroethylene, and toluene.⁹² Intentional inhalation of CCl_4 is rarely reported, but its toxic metabolite, the trichloromethyl radical, created by the cytochrome CYP2E1, can covalently bind to hepatocyte macromolecules and cause lipid peroxidation.¹¹⁹ This has led to a postulated antidotal role for hyperoxia and hyperbaric oxygen supported by some rat studies and human case reports.^{32,146} Histologically, the potentially fatal centrilobular necrosis that occurs with CCl_4 mimics acetaminophen toxicity and antidotal N-acetylcysteine (NAC) therapy has been explored. Animal studies on the efficacy of NAC in preventing CCl_4 –induced hepatotoxicity have yielded mixed results.^{38,41} There are no clinical trials in humans, but a case series suggest a protective role for NAC.¹²³ Two cases of centrilobular hepatic necrosis following inhalation of trichloroethylene are reported. In a case series of 34 serum-confirmed inhalant deaths, two of the three who died from trichloroethane and trichloroethylene inhalation had cirrhosis of the liver at autopsy. None of the victims of other inhalants had cirrhosis.⁵⁴ Inhalation of either toluene or one of the many halogenated hydrocarbons is associated with elevated liver enzymes and hepatomegaly that generally return to pre-exposure condition within 2 weeks of abstinence.^{7,69,74,86,105,108}

Most reported kidney toxicity is associated with toluene inhalation. Prolonged toluene inhalation was said to cause a distal renal tubular acidosis (RTA), resulting in hypokalemia. However, distal RTA is typically associated with a hyperchloremic metabolic acidosis and a normal anion gap, whereas toluene abuse may be associated with an increased anion gap. Production of hippuric acid, a toluene metabolite, plays an important role in the genesis of the metabolic acidosis.³⁵ Hippurate excretion, usually expressed as a ratio to creatinine, rises dramatically with toluene inhalation.⁹⁸ The excretion of abundant hippurate in the urine unmatched by ammonium mandates an enhanced rate of excretion of sodium and potassium cations. Continued loss of potassium in the urine leads to hypokalemia. Toluene is rapidly metabolized to hippuric acid and the hippurate anion is swiftly cleared by the kidneys, thus leaving the hydrogen ion behind. This prevents the rise in the anion gap that would normally occur with an acid anion other than chloride, resulting in a normal anion gap.

In some cases, the loss of sodium causes extracellular fluid volume contraction and a fall in the glomerular filtration rate, which may transform the metabolic acidosis with a normal anion gap into one with a high anion gap caused by the accumulation of hippurate and other anions.³⁵ Other renal abnormalities of uncertain etiology are associated with toluene inhalation, including hematuria, albuminuria, and pyuria. Glomerulonephritis associated with hydrocarbon inhalation is also reported and is a result of antglomerular basement membrane antibody-mediated immune complex deposition.^{17,147,162}

Toluene-abusing patients may present with profound hypokalemic muscle weakness. In a study of 25 patients admitted to the hospital following inhalant abuse, nine presented with muscle weakness.¹³⁸ The mean serum potassium concentration was 1.7 mEq/L, and six of these patients also had rhabdomyolysis. Four patients were quadriplegic on presentation; of these, two were initially diagnosed erroneously with Guillain-Barré syndrome. The patients had inhaled toluene 6 to 7 hours per day for 4 to 14 days prior to presentation.¹³⁸

Acute dermatologic and upper airway toxicity is associated with the inhalation of fluorinated hydrocarbons. First- and second-degree burns of the face, neck, shoulder, and chest are reported in a 12 year-old girl inhaling a computer cleaner containing difluoroethane.¹⁰¹ Pyrolysis of difluoroethane may yield hydrofluoric acid burns.⁵² Vesicular lesions resembling frostbite and massive, potentially life-threatening edema of the oropharyngeal, glottic, epiglottic, and paratracheal structures are also reported.^{1,81,95} This is caused by the cooling of the gas associated with its rapid expansion once it is released from its pressurized container. With chronic abuse of volatile hydrocarbons, patients may develop severe drying and cracking around the mouth and nose as a consequence of a defatting dermatitis known as “huffer’s eczema.” Other manifestations of chronic irritation include recurrent epistaxis, chronic rhinitis, conjunctivitis, halitosis, and ulceration of the nasal and oral mucosa.⁹⁸

Bone mineral density was significantly lower in 25 adolescent chronic glue sniffers compared with that of healthy controls.⁴⁵ In a mouse model, chronic exposure to toluene significantly reduced bone mineral density.⁵ Methylene chloride (dichloromethane), most commonly found in paint removers and degreasers, is unique among the halogenated hydrocarbons in that it undergoes metabolism in the liver by CYP2E1 to carbon monoxide.¹¹⁰ In addition to acute CNS and cardiac manifestations, inhalation of methylene chloride is associated with delayed onset and prolonged duration of signs and symptoms of carbon monoxide (CO) poisoning. The CO metabolite is generated 4 to 8 hours after exposure and its apparent half-life is 13 hours, significantly longer than that of CO following inhalation (Chap. 125).^{10,139} Methanol toxicity is reported following intentional inhalation of methanol-containing carburetor cleaners.^{53,88,94} Significant findings may include hyperemic optic discs on funduscopic examination, metabolic acidosis, and CNS and respiratory depression (Chap. 109). Methanol-containing carburetor cleaners may also contain significant amounts of toluene (43.8%), methylene chloride (20.5%), and propane (12.5%). These xenobiotics may potentiate CNS depression and contribute to the toxicity associated with these products.

Chronic inhalation of the solvent n-hexane, a petroleum distillate and a simple aliphatic hydrocarbon found, for example, in rubber cement, can cause a sensorimotor peripheral neuropathy. Toxicity is mediated via a metabolite, 2,5-hexanedione, which interferes with glyceraldehyde-3-phosphate dehydrogenase-dependent axonal transport, resulting in axonal death.⁴⁴ Numbness and tingling of the fingers and toes is the most common initial complaint; progressive, ascending loss of motor function with frank quadriparesis may ensue.³⁶ Sural nerve biopsy shows axonal swelling and axonal loss, with secondary loss of myelin, probably as a result of retraction by axonal swelling, and accumulation of neurofilaments.⁸² Nerve conduction studies show marked slowing and blockade (Chap. 24).^{36,82}

Reports of polyneuropathy associated with chronic gasoline inhalation date to the 1960s and describe a symmetric, progressive, sensorimotor neuropathy with occasional superimposed mononeuropathies.^{31,75} Initially, these deficits were attributed to the presence of tetraethyl lead as an “anti-knocking” agent in gasoline, but cases following abuse of unleaded gasoline are also reported.^{31,126} n-Hexane is present in gasoline in concentrations of up to 3% and is thought to be the likely mediator of gasoline neuropathy.¹⁵³

Teratogenicity. Fetal solvent syndrome (FSS) was first reported in 1979.¹⁴⁵ The authors described a 20 year-old primigravida woman with a 14 year history of solvent abuse defined as “daily” and “heavy” who gave birth to an infant exhibiting facial dysmorphism, growth retardation, and microcephaly, a constellation of findings that resembles fetal alcohol syndrome (FAS). Since then, many cases and case series have been reported.^{4,68,124,155} A general limitation of these case series is their reliance on self-reporting of substance abuse. In a number of cases included for analysis of teratogenic effects, mothers admit to use during pregnancy of other potential teratogens, including ethanol, cocaine, heroin, and phenobarbital.^{4,155} Cases purported to represent inhalant abuse in the absence of other drug abuse, particularly ethanol, are not verified by laboratory testing. A small study of infants born to mothers with a self-reported history of chronic solvent abuse found 16% had major anomalies, 12.5% had facial features resembling FAS, and 3.6% had cleft palate.¹²⁴ Craniofacial abnormalities common to both FAS and FSS include small palpebral fissures, thin upper lip, and midfacial hypoplasia. Features of FSS that distinguish it from FAS include micrognathia, low-set ears, abnormal scalp hair pattern, large anterior fontanelle, and downturned corners of the mouth.¹⁴⁵ Hypoplasia of the philtrum and nose are more characteristic of FAS.¹¹³ Compared with matched controls, infants born to mothers who report inhalant abuse are more

likely to be premature, have low birth weight, have smaller birth length, and have small head circumference.^{4,155} Follow-up studies of these infants show developmental delay when compared with children matched for age, race, sex, and socioeconomic status.^{4,68} A rat model of toluene abuse embryopathy found a significant reduction in the number of neurons within each cortical layer, as well as abnormal neural migration.⁶⁰ In animal models of inhalant abuse, exposure to brief, repeated, high concentrations of toluene significantly increases rates of growth restriction, minor malformations, and impaired motor development.^{24,73} In another rat model of maternal inhalant abuse, toluene concentrations in fetal brain tissue, the placenta, and amniotic fluid increased in a concentration-dependent manner.²⁶

Withdrawal. Observed similarities in the acute effects of inhalants compared with other CNS depressants have suggested similar patterns of tolerance and withdrawal. Rodent models of inhalant abuse with toluene and TCE show evidence of physical dependence that manifests as an increase in handling-induced seizures on cessation of inhalation.^{48,154} In addition, these studies demonstrate cross-tolerance of the benzodiazepine diazepam with the motor-stimulating effects of TCE and, to a lesser degree, with toluene. Inhalant abusers have themselves described tolerance with weekly usage in as little as 3 months.⁶² Withdrawal symptoms, including irritability, insomnia, craving, nausea, tremor, and dry mouth lasting 2 to 5 days after last use, are described.¹²⁸

VOLATILE ALKYL NITRITES

Methemoglobinemia caused by inhalation of amyl, butyl, and isobutyl nitrites is well reported.^{28,89} Nitrites are strong oxidants that may induce hemoglobin oxidation from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. Patients may present with signs and symptoms of methemoglobinemia, including shortness of breath, cyanosis, tachycardia, and tachypnea (**Chap. 127**). Eye pain, transient increased intraocular pressure, and progressive bilateral visual loss are reported following use of amyl nitrite.^{6,112,114}

Nitrous Oxide

Reported deaths associated with abuse of nitrous oxide (N_2O) appear to be caused by secondary effects of N_2O , including asphyxiation and motor vehicle collisions while under the influence, and not a direct toxic effect.^{141,150} Investigations following deaths associated with N_2O have found that many of the people who died were discovered with plastic bags over their heads, in an apparent attempt to both prolong the duration of effect and increase the concentration of the inhalant.¹⁵⁰ Autopsy findings in these cases were consistent with asphyxiation: acute respiratory distress syndrome, cardiac petechiae, and generalized visceral congestion.^{141,150} Laboratory simulation of a reported death in which the victim was found with a plastic bag over his head with a belt fastened loosely around his neck and a spent whipped cream canister within the plastic bag showed that N_2O displaces oxygen in a closed space.¹⁵⁰ In addition, N_2O concentrations in this simulation were above 60%; at concentrations of N_2O above 50%, the normal hypoxic response is diminished.¹⁵⁰ The combined effects of displaced oxygen and a blunted hypoxic drive may increase the risk of asphyxia.

Chronic abuse of N_2O is associated with neurologic toxicity mediated via irreversible oxidation of the cobalt ion of cyanocobalamin (vitamin B_{12}). Oxidation blocks formation of methylcobalamin, a coenzyme in the production of methionine and S-adenosylmethionine, required for methylation of the phospholipids of the myelin sheaths. In addition, cobalamin oxidation inhibits the conversion of methylmalonyl to succinyl coenzyme A. The resultant accumulation of methylmalonate and propionate can result in synthesis of abnormal fatty acids and their subsequent incorporation into the myelin sheath (**Chap. 68**).¹¹⁵ Case reports and small case series in humans following self-reported chronic, heavy abuse of N_2O describe the development of a myeloneuropathy resembling the subacute combined degeneration of the dorsal columns of the spinal cord of classic vitamin B_{12} deficiency.^{19,84,149} Presenting signs and symptoms reflect varying involvement of the posterior columns, the corticospinal tracts, and the peripheral nerves. Numbness and tingling of the distal extremities is the most common presenting complaint. Physical examination may reveal diminished sensation to pinprick and light touch, vibratory sensation and proprioception, gait disturbances, the Lhermitte sign (electric shock sensation from the back into the limbs with neck flexion), hyperreflexia, spasticity, urinary and fecal incontinence, and extensor plantar response.^{33,115} Among reported patients with N_2O -associated neurotoxicity who had documented concentrations of vitamin B_{12} , approximately 50% were low.^{19,33,84,135,149} In the few patients who underwent Schilling tests to evaluate for potential vitamin B_{12} deficiency results were normal.^{84,149} MRI of the spinal column may reveal enhancement and edema of the central and dorsal aspects of the spinal cord.¹¹⁷ Nerve conduction studies and electromyography typically revealed a distal, axonal sensorimotor polyneuropathy.^{33,84,149}

LABORATORY AND DIAGNOSTIC TESTING

Routine urine toxicology screens are unable to detect inhalants or their metabolites. Although most volatile inhalants can be detected using gas chromatography, the likelihood of detection is limited by the dose, time to sampling, and method of specimen storage. Blood is the preferred specimen, but urinalysis for metabolites, including hippuric acid (the toluene metabolite) and methyl hippuric acid (the xylene metabolite), may extend the time until the limit of detection is reached.^{29,83} Specimens should be stored at a temperature between 23°F (−5°C) and 39.2°F (4°C).²⁵ Testing is not readily available at most institutions and the need to send the specimen to a reference laboratory limits the clinical utility in most situations. A thorough history and physical examination and careful questioning of the friends and family of the patient are probably more helpful in cases of suspected inhalant abuse.

Depending on the patient's signs and symptoms, additional diagnostic testing may be indicated, including electrocardiography, chest radiography, and laboratory studies (electrolytes, liver enzymes, and blood pH). Inhalation of some xenobiotics presents unique diagnostic considerations (Table 84–3). Routine laboratory testing, including cerebrospinal fluid analysis, is unremarkable in patients with inhalant-induced leukoencephalopathy. Computed tomography of the head is generally normal until late in the disease when diffuse hypodensity of white matter becomes evident. T2-weighted MRI with its superior resolution of white matter is the diagnostic study of choice. Standard MRI does not detect initial changes caused by toluene leukoencephalopathy; measurement of N-acetyl aspartate (NAA), a marker of CNS axonal damage, with magnetic resonance spectroscopy may assist with earlier detection. A decrease in NAA concentration, usually expressed as the ratio of NAA to creatinine (NAA:Cr), may serve as a marker of axonal damage.⁵⁰

TABLE 84–3. Inhalants with Unique Clinical Manifestations

<i>Inhalant</i>	<i>Clinical Manifestations</i>
Toluene	Hypokalemia Hepatotoxicity Leukoencephalopathy (chronic)
1,1,1-Trichloroethane, trichloroethylene	Hepatotoxicity
Methylene chloride	Carbon monoxide poisoning
Carburetor cleaner	Methanol poisoning
Alkyl nitrites (amyl, butyl, isobutyl)	Methemoglobinemia Vision loss
<i>n</i> -Hexane	Peripheral neuropathy (chronic)
Nitrous oxide	Myeloneuropathy (chronic)

MANAGEMENT

Management begins with assessment and stabilization of the patient's airway, breathing, and circulation (the “ABCs”). The patient should be attached to a pulse oximeter and cardiac monitor. Oxygen should be administered and the patient should be treated with nebulized β -adrenergic agonists if wheezing is present. Early consultation with a regional poison center or medical toxicologist may assist with identification of the xenobiotic and patient management.

Cardiac dysrhythmias associated with inhalant abuse carry a poor prognosis. Sudden death following use is not limited to novices and there appears to be no premonitory signal to the user.^{8,11,105} Life-threatening electrolyte abnormalities must be considered and corrected in the patient presenting with dysrhythmia. Patients with nonperfusing rhythms should be managed following standard management with defibrillation. There are no evidence-based treatment guidelines for the management of inhalant-induced cardiac dysrhythmias, but β -adrenergic antagonists are thought to offer some cardioprotective effects to the sensitized myocardium.¹⁰⁶ Propranolol and esmolol both have been used successfully in treatment of ventricular dysrhythmias following inhalant abuse.^{58,102}

Fluid and electrolyte abnormalities should be sought and corrected early. In the course of management, other complications, including methemoglobinemia, elevated carboxyhemoglobin, and methanol toxicity, should be managed with the appropriate antidotal therapy. Patients with respiratory symptoms persisting beyond the initial complaints of gagging and choking should be evaluated for hydrocarbon pneumonitis and treated supportively (Chap. 108).

With abstinence, cognitive and neuroimaging changes associated with toluene-induced leukoencephalopathy may initially be partially reversible; beyond a poorly defined period, these changes are irreversible.^{43,50} Cessation of abuse is the most important therapeutic intervention in patients with *n*-hexane–induced neuropathy. In N₂O-induced myeloneuropathy limited anecdotal evidence supports the coadministration of vitamin B₁₂ (1000 μ g intramuscularly) and methionine (1 g

orally).^{33,127,135}

Agitation, either from acute effects of the inhalant or from withdrawal, is safely managed with a benzodiazepine. In the vast majority of patients, symptoms resolve quickly and hospitalization is not required. The potential toxicity of inhalants should be reinforced and patients should be referred for counseling. Subsets of users who meet the criteria for inhalant dependence and inhalant-induced psychosis require inpatient psychiatric care. Pharmacotherapy with carbamazepine or the antipsychotics haloperidol, risperidone, and aripiprazole appears beneficial to some patients with an inhalant-induced psychotic disorder.^{46,67,99} Case reports describe successful treatment of inhalant dependence with lamotrigine, which inhibits excitatory glutamatergic tone, and with buspirone, an atypical anxiolytic.^{107,131} Drug use treatment programs for inhalant abuse are scarce and few providers have special training in this area.¹³

SUMMARY

- Inhalants are a heterogeneous group of xenobiotics that include the volatile hydrocarbons, alkyl nitrites, and nitrous oxide.
- The incidence of inhalant abuse is greatest among adolescents.
- The CNS is the intended target for the inhalant users; early effects include euphoria, hallucinations, headache, and dizziness.
- Acute cardiotoxicity is manifested most dramatically in “sudden sniffing death.”
- The diagnosis is largely clinical; further diagnostic testing should be guided by the patient’s presenting complaint.
- Management begins with basic life support and care is generally supportive.
- Cessation of use is the only known treatment for many manifestations of chronic toxicity.

85 NICOTINE

Sari Soghoian

HISTORY AND EPIDEMIOLOGY

The tobacco plant is native to the Americas, and its use most likely predates the Mayan empire. In 1492 Christopher Columbus and his crew were given tobacco by the Arawaks, but reportedly threw it away not knowing any use for it. Ramon Pane, a monk who accompanied Columbus on his second voyage to America, is credited with introducing tobacco to Europe.⁸³

The principal alkaloid, nicotine, is still primarily derived from members of the genus *Nicotiana*, collectively known as the tobacco plant, in the family Solanaceae. The most important species in human use today is *Nicotiana tabacum* and the primary method of nicotine exposure is cigarette smoking. Because of the highly addictive properties of nicotine, the global disease burden related to cigarette use is staggering. Cigarette smoking increases rates of chronic obstructive pulmonary disease (COPD), cardiovascular disease, pulmonary infections, macular degeneration, and cancers, and causes more than 5 million deaths worldwide per year. Chronic nicotine exposure causes cardiovascular damage related to catecholamine release and vasoconstriction, and directly promotes angiogenesis, neuroteratogenicity, and possibly some cancers.⁵¹ However, there are more than 3000 components to tobacco smoke and nicotine per se may not be the crucial determinant of the total health burden associated with its use.

Although the long-term effects of cigarette smoking and tobacco dependency are significant, this chapter is concerned with the sources, effects, and management of acute toxicity referable to nicotinic receptor stimulation and cholinergic activation. Reviews of case data from the National Poison Data System suggest that cigarettes are by far the most common vehicle implicated in acute nicotine exposures and poisoning in the United States.² Smoking cessation products containing nicotine are increasingly available and some of the more novel smokeless tobacco products have the appearance of candy, raising concern about the potential for unintentional poisoning of young children, in particular.²¹

Compared with other xenobiotics, exposure to nicotine containing products is nonetheless a relatively rare cause of acute poisoning. For example, over a period of 27 years from 1983 to 2009, tobacco products accounted for 217,340 calls, or 0.37%, of all pediatric exposures reported to poison centers in the United States,² and accounted for 0.7% of all unintentional poisoning cases in children treated in US hospital emergency departments in one national estimate.³¹ Although fatalities are reported, most patients with nicotine exposure have a benign course, with only mild to moderate symptoms and an infrequent need for hospitalization.

Nicotine receptor partial agonists/antagonists are a relatively new class of drug mimicking the physiologic effects of nicotine. A 2-year review of poison center data from the California Poison Control System found 36 calls regarding human exposures to varenicline (Chantix), which was approved in 2006 by the US Food and Drug Administration (FDA) as a smoking cessation aid.⁴⁶ Of these, 17 cases had no outcome data or involved coingestions. Nine of the remaining cases involved unintentional exposure in children younger than 6 years of age, one of whom was hospitalized; none experienced major adverse events.

Use of nicotine as an insecticide is no longer in widespread use in the United States, but are still used in other countries and can be purchased from some online retailers. The neonicotinoids are a relatively new class of insecticide developed in the last quarter century, and epidemiologic data about their role in acute pesticide poisoning are still limited. A retrospective review of poison center data from Thailand found no reports of neonicotinoid exposures before 1993.⁷¹ Between 1993 and 2007 there were a total of 70 cases, including two deaths. The number of exposures reported annually increased dramatically after 2002, suggesting that neonicotinoid insecticides may still be an emerging cause of acute

pesticide poisoning. However, in the year with the highest case incidence, these insecticides still represented less than 3% of all pesticide exposures reported.

Dermal exposure to tobacco plants during harvest remains an important source of occupational nicotine toxicity known as green tobacco sickness (GTS). GTS was first reported in 1970 among tobacco workers in Florida.⁸⁷ In 1992, the US Centers Disease and Control and Prevention estimated the crude 2-month incidence rate of hospital treated GTS was 10 per 1000 workers in a five-county area in Kentucky.⁶² Overall prevalence estimates among seasonal and migrant farmworkers are as high as 25% to 40% of workers.^{3,5,73}

PHARMACOLOGY/PHARMACOKINETICS

The pharmacologic characteristics of nicotine are listed in Table 85–1. Nicotine is well absorbed from the respiratory tract, mucosal surfaces, skin, and the intestines. Nicotine is a weak base (pKa = 8.0) and is more readily absorbed in an alkaline environment. Many tobacco and nicotine replacement products are therefore buffered to alkaline pH to facilitate absorption.

TABLE 85–1. Pharmacologic Characteristics of Nicotine

Absorption	Lungs, oral mucosa, skin, intestinal tract; increased in more alkaline environment
Volume of distribution	Approximately 2.6 L/kg
Protein binding	About 5%
Metabolism	80%–90% hepatic; remainder in lung, kidney; principal (inactive) metabolite is cotinine
Half-life	Nicotine: 1–4 hours, decreases with repeated exposure Cotinine: ~ 20 hours
Elimination	2%–35% excreted unchanged in urine

Nicotine from cigarette or cigar smoke is carried on inhaled tar particles into the lungs where a large alveolar surface area allows rapid absorption into the pulmonary circulation. In the bloodstream, nicotine is about 69% ionized at pH 7.4 and less than 5% is bound to plasma proteins. Distribution to body tissues is rapid and extensive, with an average volume of distribution of about 2.6 L/kg.⁶ Nicotine readily crosses the placental barrier and is secreted in breast milk. Metabolism occurs primarily in the liver via P450 cytochrome oxidases CYP2A6 and CYP2D6, aldehyde oxidase, flavin monooxygenase, and by glycosylation. About 70% of circulating nicotine is metabolized to cotinine, and much smaller amounts to nornicotine, nicotine-1-N-oxide, nicotine glucuronide, and 2'-hydroxynicotine.

Peak plasma concentrations of nicotine and cotinine are influenced most strongly by individual variations in clearance.^{10,11} Hepatic nicotine metabolism is inducible and nicotine-dependent individuals metabolize the drug more rapidly than naïve ones.⁴⁰ Nicotine metabolism may also be linked to race and sex. Asians and African Americans metabolize nicotine more slowly than Caucasians, and they have prolonged cotinine clearance in the urine.^{10,52,68} Women metabolize nicotine faster than men, which is further accelerated by oral contraceptive use and pregnancy, and is most likely mediated by an influence of estrogen on CYP2A6 activity.⁴⁰

Renal excretion of unchanged nicotine accounts for 2% to 35% of total nicotine elimination,¹⁵ and this is pH dependent. Nicotine is reabsorbed in the proximal tubule and acidification of the urine enhances elimination. The half-life of nicotine in the body is 1 to 4 hours and it decreases with repeated nicotine exposure such as with habitual cigarette smoking. Cotinine and trans-3'-hydroxycotinine are eliminated in the urine as glucuronide esters independent of urine pH. The elimination half-life of cotinine is approximately 20 hours and therefore urinary cotinine is a more useful marker of nicotine exposure. The apparent elimination half-life of nicotine after transdermal patch removal is longer than that noted with nicotine exposure by other routes,⁴³ but this is most likely because a dermal reservoir of drug is established during patch use, from which absorption continues after removal.

Cigarette smoking modulates the bioavailability and effectiveness of numerous medications through effects on drug absorption, metabolism, or pharmacodynamics. Cigarette smoking induces CYP1A2 and accelerates the metabolism of caffeine, clozapine, olanzapine, tacrine, theophylline, and erlotinib.^{39,42} This may not be an effect of nicotine. For example, intravenous nicotine administration does not affect theophylline metabolism.¹² Smokers also have diminished effectiveness

of opioids, benzodiazepines, β -adrenergic antagonists, and nifedipine,¹⁹ and are more likely to fail antacid and H₂-blocker therapy for peptic ulcer disease.¹² However, these interactions have also not been clearly linked to an effect of nicotine per se.

The LD₅₀ of nicotine has been estimated at about 0.5 to 1 mg/kg in adults.^{33,35,54} Severe toxicity is reported with ingestion of less than 2 mg in a child,^{59,80} and this dose is sufficient to produce mild symptoms in an unhabituated adult. Children younger than 6 years of age who ingest one or more cigarettes, or three or more cigarette butts, generally develop symptoms of nicotine toxicity.⁸⁰ A retrospective review of 10 pediatric cigarette ingestions found that all four patients with symptoms requiring medical evaluation and treatment had ingested at least two entire cigarettes.⁵⁴

Acute tolerance to nicotine develops in smokers who take in small doses of nicotine regularly throughout the day. Sensitization to the effects of nicotine is restored with overnight abstinence.^{9,40} Tolerance may also develop in tobacco workers with regular exposure to tobacco plant leaves. However, the phenomenon of acute tolerance, along with considerable genetic variability in nicotine metabolism, implies a range of susceptibility to drug effect.

SOURCES AND USES OF NICOTINE

Cigarettes and Cigars

The amount of nicotine contained in a single cigarette is highly variable, ranging from less than 10 mg in a “low nicotine” cigarette to 30 mg in some European cigarettes (Table 85–2). Since most nicotine is either lost in the sidestream (secondhand) smoke, or left in the filter, the absorbed nicotine yield from a smoked cigarette is much less than this, on the order of 0.05 to 3 mg/cigarette.³⁰ The amount of nicotine absorbed by a particular individual from a single smoked cigarette is highly variable among smokers and depends on the puff rate, volume, the depth and duration of inhalation, and the size of the residual.⁵⁵ Cigars have higher nicotine content than cigarettes (Table 85–2) and potentially greater absorption since cigar and pipe tobacco is typically air cured to achieve a high pH.

TABLE 85–2. Sources of Nicotine

Source	Content (mg)	Delivered (mg)
1 cigarette	10–30	0.05–3
1 cigarette butt	5–7	—
1 cigar	15–40	0.2–1
1g snuff (wet)	12–16	2–3.5
1g chewing tobacco	6–8	2–4
1 piece nicotine gum	2 or 4	1–2
1 nicotine patch	8.3–114	5–22 over 16–24 hours
1 nicotine lozenge	2 or 4	2–4
1 nicotine nasal spray	0.5	0.2–0.4
30-mL bottle of nicotine liquid refill for e-cigarette cartridges (30, 50, 100 mL bottles also sold)	0–<36 mg/mL	<43.2 μ g/100mL “puff” of nicotine mist

The potential for nicotine toxicity from smoking is limited since peak effects by this route will occur within seconds and tend to limit further intake of drug. Most reports of acute nicotine toxicity referable to cigarette exposure are associated with cigarette and cigarette butt ingestion, usually by young children.^{61,70,79} Although uncommon, severe toxicity from cigarette^{14,80} ingestion is well reported. Ingesting cigarette soakage water has been recommended on the Internet as a “safe and effective” means of suicide, and several cases are reported.^{23,76} Intravenous injection of cigarette soakage is also reported.³⁸

Oral Tobacco

Snuff and chewing tobacco are still widely employed by users of smokeless tobacco products,²¹ despite clear associations

with periodontal disease, dental cavities, and up to a 48 times greater risk of oropharyngeal cancers compared with people who do not use tobacco products.²² Snuff, or dip, is a finely ground and sometimes flavored tobacco preparation often sold in small teabaglike pouches that users insert between their lower lips and gums. Chewing tobacco consists of shredded, twisted, or “bricked” dried tobacco leaves. Because nicotine is a weak base, smokeless tobacco is buffered to facilitate buccal absorption. In one survey of major US brands, the pH of marketed oral tobacco products ranged from 5.24 to 8.35, and the nicotine content ranged from 3.37 to 11.04 mg/g.⁶⁰ Acute nicotine toxicity from smokeless tobacco is rarely reported in adults. A 14 month-old boy had muscle fasciculations and lethargy after ingesting material out of his father’s spittoon, but recovered within 24 hours with supportive care.³⁵ Rectal administration of moist snuff as a treatment for migraine headache resulted in significant toxicity in one patient.⁴⁴ Presumably the relatively alkaline environment of the rectum facilitated absorption of a high dose.

Gum

Nicotine gum has been available without a prescription as an aid to smoking cessation in the United States since 1996. It is sold in 2 mg and 4 mg strengths per piece. Approximately 53% to 72% of the nicotine in the gum is absorbed. It is buffered to an alkaline pH to facilitate buccal absorption. The gum is supposed to be chewed until mouth and throat tingling and a peppery taste develops, signaling nicotine release. The gum is then “parked” in the cheek until the sensation subsides, at which time it may be chewed again to release more drug.⁶⁵ If used correctly, serum nicotine concentrations rise gradually to a level slightly lower than normally achieved by cigarette smoking.⁶⁵ If the gum is swallowed whole, then serum concentrations rise even more slowly because the acidic environment of the stomach delays absorption.¹² Conversely, if the gum is chewed vigorously and saliva is swallowed, then nicotine concentrations may rise rapidly and adverse reactions may occur.⁸⁰

Lozenges

Nicotine lozenges containing 2 and 4 mg of nicotine are available for purchase without a prescription in the United States. The potential for rapid absorption of nicotine as a bolus dose from chewing the lozenge is a concern.

Transdermal Patches

Nicotine patches have been FDA approved for purchase without prescription in the United States since 1996. Most nicotine transdermal delivery systems are designed to deliver 7, 14, or 21 mg of nicotine over 24 hours.³⁷ Because many patch users have difficulty sleeping, experience vivid dreams, or have nightmares if they wear the patch overnight, systems designed to be applied for only 16 hours are now made. Several reports document consequential nicotine toxicity related to nicotine patch misuse. Toxicity may occur in people who continue to smoke cigarettes after beginning therapy with the nicotine patch. Children have developed symptoms after exploratory self-application of one or more patches to the skin,^{85,88} and concurrent use of multiple patches has been used as a means of suicide.^{47,81,87} Severe toxicity may also occur if patches are punctured—for example, by biting or tearing—thus allowing delivery of excess content.⁸⁸ The patch reservoirs contain an estimated 36 to 114 mg per patch.⁶⁴ This amount exceeds the estimated LD₅₀ for nicotine in humans of 1 mg/kg for most children and many adults.

Spray/Inhaler

A nicotine spray has been available since 1996 to aid efforts at smoking cessation. The most commonly reported adverse effects during initiation of therapy are due to local irritation and include rhinorrhea, lacrimation, sneezing, and nasal and throat irritation.⁴¹ One spray delivers 0.5 mg of nicotine and the recommended dose is two sprays every 30 to 60 minutes as needed. The absorption is about 50% of the delivered dose and may be diminished or delayed by rhinitis or by α -adrenergic agonist decongestants.⁵⁰ No report of acute nicotine toxicity from nicotine inhalers has been published to date.

Electronic Cigarettes

Electronic cigarettes, or e-cigarettes, are a relatively new nicotine delivery product now widely available in various strengths and flavors.⁹¹ The devices resemble cigarettes and contain a rechargeable battery pack along with a small heating element attached to a reservoir of liquid nicotine. An electronic airflow sensor activates the heating element when the user inhales, allowing release of a “puff” of nicotine-containing vapor. An FDA analysis of cartridges found that identically labeled products contained variable amounts of nicotine and a number of potentially harmful contaminants.⁸² The potential for harm is evident, particularly since e-cigarette sales are still unrestricted in many states and large-volume liquid nicotine replacement fluid bottles (used to refill e-cigarette cartridges) are increasingly available. The nicotine content of these bottles is substantial. Formulations of different strengths are sold; the highest strength preparations may contain over a gram

of nicotine per 30mL bottle, raising serious concerns about the risk of both unintentional and intentional toxic exposures. Analysis of calls to US poison centers about e-cigarette exposures has shown substantial increase between the years 2010 and 2014, with significantly greater adverse effects reported compared to calls about cigarette exposures.^{16a}

Nicotine Receptor Partial Agonists (Varenicline, Cytisine)

Nicotine receptor partial agonists are used to aid smoking cessation. Theoretically, they work by reducing smoking satisfaction (agonist antagonism effect) while helping to maintain moderate levels of central dopamine release (partial agonist effect). Cytisine is a plant-derived xenobiotic with a chemical structure similar to nicotine that has been used in East and Central Europe as a smoking cessation drug since the 1960s under the trade name Tabex (Sopharma Pharmaceuticals). Despite its widespread use, it has not been well studied for its safety, efficacy, pharmacokinetics, and pharmacodynamics in humans.²⁹ Varenicline (marketed as Chantix in the United States and Champix in Europe) was approved as a prescription-only aid to smoking cessation in 2006. Several randomized controlled trials demonstrated efficacy in controlling nicotine cravings and evidence suggests that varenicline increases the probability of successful abstinence from smoking.¹⁶ In 2009, the FDA mandated a black box warning due to an association with increased risk of depression or suicidal behavior. There is still limited experience with effects or outcomes after acute overdose.

Plants/Leaves

Residual moisture or dew drops on tobacco leaves may contain as much as 9 mg of nicotine per 100 mL.³⁴ Sweat wrung out of the shirts worn by workers during tobacco harvest in one study contained up to 98 mg/mL of nicotine.³⁴ Risk factors for GTS include younger age, working in wet tobacco, and a relative lack of work experience.^{3,5,58,62} These factors may all be related to a lack of nicotine tolerance. The use of impermeable garments or other barrier protection is the only protective factor consistently noted to be useful across multiple studies.^{4,58,62}

Salts (Pesticides)

Nicotine in the form of tobacco extracts was first reported as effective for pest control in 1690. In 1886 a mixture of tobacco and soapsuds was advocated for aphid control, but it was not until 1912 that the first commercial nicotine insecticides were developed. Crop dusting with nicotine sulfate began in 1917, although at the time this was mostly accomplished by horse-drawn carriage.⁶⁹ The most widely known application of 40% nicotine sulfate, BlackLeaf 40, was discontinued in 1992. Nicotine is still available as a restricted use pesticide, and a 14% preparation of nicotine is still marketed as a greenhouse smoke fumigator.⁶⁶ Because nicotine pesticides are highly concentrated, the ingestion of even small amounts may produce serious toxicity, including catastrophic brain injury⁷⁵ and death.⁴⁸

Neonicotinoids

The neonicotinoids are a relatively new class of insecticides with theoretical safety by markedly reducing the affinity for vertebrate nicotinic receptors as compared with those in insects.⁸⁴ Neonicotinoid compounds include the heterocyclics nithiazine, imidacloprid, thiacloprid, and thiamethoxam; and the acyclics nitenpyram, acetamiprid, clothianidin, and dinotefuran. Experience with human poisoning is still limited.

Miscellaneous

Tobacco has been used for medicinal and therapeutic purposes in many societies for some time. Tobacco extract and tobacco smoke enemas were used in the pre-Columbian Americas by many tribes for both medicinal and spiritual purposes. They are still recommended by some naturopaths and folk healers as a remedy for constipation, urinary retention, pin worm and “hysterical convulsions.” Nicotine has also been recommended as a treatment for migraine, on the basis of its vasoconstrictive properties.³⁶ Nicotine poisoning has resulted from “therapeutic misadventure” in several documented cases.^{33,44,45} For example, acute nicotine toxicity occurred in an 8 year-old boy after application of a homemade remedy for eczema made from a mixture of tobacco leaves, lime juice, and freeze dried coffee.²⁶

PATHOPHYSIOLOGY

Nicotine mimics the effects of acetylcholine release by binding to nicotinic receptors (nAChR) in the brain, spinal cord, autonomic ganglia, adrenal medulla, neuromuscular junctions, and chemoreceptors of the carotid and aortic bodies (Chap. 14). Activation of nAChR in the CNS directly stimulates neurotransmitter release. When nicotine binds to this receptor, an ion channel opens allowing an influx of cations, mostly sodium and calcium. Voltage-gated calcium channels are then activated leading to further influx of calcium, and a variety of downstream effects, including depolarization.

At doses generally produced by cigarette smoking there is stimulation of the reticular activating system and an alerting pattern on electroencephalogram.⁹² Nicotine-stimulated release of dopamine occurs in the mesolimbic area, the corpus striatum, the prefrontal cortex, and in the nucleus accumbens; it is an important mediator of nicotine addiction.⁵⁶ Nicotine also stimulates glutaminergic activation and the GABAergic inhibition of dopaminergic neurons in the hippocampus, basal forebrain, and ventral tegmental area of the midbrain.^{8,28} These pathways, along with endogenous cannabinoid and opioid systems, are also thought to be important neuromodulatory pathways for drug-induced reward, dependence, and withdrawal.^{53,56,67} Norepinephrine, acetylcholine, GABA, serotonin, glutamate, and endorphins are all released by nicotine and are associated with cognitive and mood enhancement as well as appetite suppression, increased basal energy expenditures and anxiety reduction.⁸

Nicotine's clinical effects are dose-dependent. Low doses of nicotine and related compounds stimulate nicotinic receptors centrally and in autonomic and somatic motor nerve fibers, resulting in sympathetic agonism. At toxic concentrations, prolonged or excessive nicotinic stimulation ultimately leads to receptor blockade ([Chap. 69](#)), with parasympathetic and neuromuscular-blocking effects.

At very high doses nicotine induces seizures. In a mouse model, nicotine-induced seizures are blocked by the nicotine-receptor antagonists mecamylamine, methyllycaconitine citrate, and hexamethonium.²⁴ However, when given to mice at slightly higher doses, these nicotine receptor antagonists are epileptogenic. The specific mechanisms by which nicotine produces seizures are unknown. A disinhibition model has been proposed in which desensitization or antagonism of central nicotinic cholinergic neurons blocks excitatory input to GABAergic neurons and a reduction of inhibitory GABAergic input to pyramidal cells then results in increased excitability and seizures.^{1,17,27,32} An alternative hypothesis is that synchronous depolarization from activation of $\alpha 7^*$ -subtype nicotinic receptors promotes kindling-induced seizures.²⁷

CLINICAL MANIFESTATIONS

Exposure to nicotine in low doses comparable to cigarette smoking in nicotine naïve patients produces fine tremor, cutaneous vasoconstriction, increased gastrointestinal motility, nausea, and increases in heart rate, respiratory rate, and blood pressure. Low-dose nicotine also increases mental alertness and produces euphoria. Because nicotine is poorly absorbed in the acid environment of the stomach, symptom onset may not occur until 30 to 90 minutes after ingestion of nicotine-containing products.

Early signs and symptoms of consequential nicotine toxicity are referable to nicotinic cholinergic excess: increased salivation, nausea, vomiting, diaphoresis, and diarrhea may all occur within minutes of systemic absorption. Vasoconstriction may manifest with pallor and hypertension. Tachycardia may also occur, and nicotine gum chewing has been implicated in the development of atrial fibrillation in several cases.^{18,74} Neurologic signs and symptoms include headache, dizziness, ataxia, confusion, and perceptual distortions. Nicotine is an irritant and ingestion of nicotine, including use of nicotine gum, may cause burning and pain in the mouth, and constriction of the throat muscles. Similarly, application of nicotine patches generally results in dermal irritation.

Data from poison centers in the United States suggests that most patients with nicotine exposure rarely display more than mild symptoms and typically have a benign course. Vomiting is the most common adverse effect reported, although agitation also occurs. The relative rarity of life-threatening symptoms may be due to autodecontamination from vomiting, or may reflect selection bias since most reported cases involve unintentional tobacco ingestion by young children. Although less common, ingestion of novel smokeless tobacco preparations, such as gums and lozenges, may be more likely to produce symptoms compared to cigarette ingestion, possibly because these are buffered to promote more rapid nicotine release.⁸⁰

Because nicotine is rapidly metabolized, patients who develop only mild symptoms are expected to recover quickly. Most patients recover fully within 12 hours. An important exception to this rule is patients with symptoms of nicotine toxicity after transdermal nicotine patch application, because a reservoir of drug may persist in the skin after patch removal and can serve as a source of ongoing absorption.

Clinical manifestations of severe poisoning are classically biphasic, reflecting early central stimulation followed by depression. Initial signs may include cardiac dysrhythmias, seizures, and muscle fasciculations in addition to the cholinergic features described above. Bradycardia, hypotension, coma, and neuromuscular blockade with respiratory failure from muscular paralysis may develop later on ([Table 85–3](#)).

TABLE 85–3. Signs and Symptoms of Acute Nicotine Poisoning

	<i>Gastrointestinal</i>	<i>Respiratory</i>	<i>Cardiovascular</i>	<i>Neurologic</i>
Early (0.25–1 hour)	Nausea Vomiting Salivation Abdominal pain	Bronchorrhea Hyperpnea	Hypertension Tachycardia Pallor	Agitation Anxiety Dizziness Blurred vision Headache Hyperactivity Confusion Tremors Fasciculations Seizures
Late (0.5–4 hours)	Diarrhea	Hypoventilation Apnea	Bradycardia Hypotension Dysrhythmias Shock	Lethargy Weakness Paralysis

Exposure to fresh tobacco leaves may produce GTS, which has been likened to the experience of seasickness. The syndrome is characterized by dizziness, headache, nausea, weakness, vomiting, diarrhea, abdominal cramps, and chills. Signs of autonomic instability may also be present in severe cases. Onset of toxicity is typically within 3 to 17 hours after exposure and the duration of illness may be several days.⁵⁷

A limited number of case reports describe the clinical course of patients poisoned by imidacloprid or other neonicotinoid pesticides. Many of the clinical manifestations may actually be attributable to the solvent N-methyl-2-pyrrolidone, which is used to formulate the pesticide and has irritant effects on skin and mucosae.⁹⁰ Published case reports of intentional imidacloprid ingestions describe an initial period of drowsiness, disorientation, dizziness, and tachycardia, with subsequent development of fever, vomiting, and leukocytosis.^{71,90} Oral, esophageal, and gastric erosions are demonstrated by upper endoscopy in several patients.^{71,72} Late-presenting bradycardia and electrolyte abnormalities have also been reported.^{71,77}

DIAGNOSTIC TESTING

Determination of serum or urinary concentrations of nicotine or its metabolites is unlikely to be helpful in the management of the acutely poisoned patient. Measurement can be made for confirmation purposes using various chromatographic techniques. Cigarette smokers typically maintain serum nicotine concentrations around 30 to 50 ng/mL during the day, but may achieve concentrations as high as 100 ng/mL.⁶³ Postmortem analyses of nicotine concentrations in blood after fatal acute intoxication range from 5.5 to 800 mg/L.²³

The presence of measurable concentrations of nicotine or cotinine in biologic samples may reflect coincidental or chronic exposure, and does not necessarily imply acute toxicity. Urinary cotinine has a longer detection window than nicotine, and is often used to document exposure to nicotine containing products, including exposure to second-hand smoke, or to guide dosage adjustments in nicotine replacement therapy.^{8,49,63} Conversely, the absence of cotinine in the urine may be used to document abstinence from tobacco products.

MANAGEMENT

Most patients with unintentional or low-dose nicotine exposures will not require medical treatment. Patients should be immediately referred for evaluation if they are symptomatic or have ingested any amount of nicotine- or neonicotinoid-containing insecticide or fluid. Children who ingest one or more cigarettes or three or more cigarette butts should also be referred for evaluation without delay. Patients with mild or no symptoms can be observed for several hours and safely discharged home if there are no complicating circumstances such as significant comorbid cardiovascular illness or intent to self-harm.

Patients with dermal exposure to wet tobacco leaves or pesticides should be undressed completely and the skin washed thoroughly with soap and copious amounts of water. Personal protective gear should be worn by medical staff charged with handling both clothes and patients prior to decontamination. Symptomatic patients should have any nicotine patches removed immediately and the skin washed with soap and water.

Vomiting is the most commonly reported adverse effect in patients with acute nicotine toxicity, and may limit absorption in some cases. Induction of emesis should be avoided since it is unlikely to be of added benefit and has the potential for harm. Orogastric lavage may be considered in patients who present immediately after large intentional ingestions of

nicotine-containing products. Activated charcoal adsorbs nicotine and can reduce absorption, but the risks of pulmonary aspiration in case of vomiting, seizure, or depressed level of consciousness tend to outweigh the potential benefit.

There is no specific antidote for nicotine toxicity. Treatment of acute nicotine toxicity is symptomatic and supportive. The first priority is to ensure airway protection and respiratory support. Atropine may be used to treat symptoms associated with parasympathetic stimulation such as excess salivation, wheezing, or bradycardia. Endotracheal intubation may be required for airway protection or to assist ventilation in severely poisoned patients. Seizures may be treated with a benzodiazepine. Hypotension should be treated with fluid boluses and an infusion 0.9% NaCl initially. Patients who fail to respond to volume infusion may require treatment with a vasopressor such as norepinephrine. Dysrhythmias should be treated according to standard protocols. Nicotine elimination is enhanced in acidic urine,¹³ but the potential risks outweigh the benefits of this elimination strategy.

SUMMARY

- The primary source of nicotine is tobacco made from the leaves of *Nicotiana* species, but chemically related tobacco substitutes and pesticides are becoming increasingly available.
- Nicotine is well absorbed after inhalation, mucosal, or dermal exposure. It is rapidly distributed to the brain where it activates nicotinic acetylcholinergic receptors, stimulates the reticular activating system, and facilitates neurotransmitter release.
- Metabolism via the hepatic cytochrome oxidase system produces pharmacologically inactive metabolites slowly excreted in urine. The half-life of nicotine in the body is about 1 to 4 hours, with more rapid clearance in individuals who are chronically exposed.
- Clinical manifestations of nicotine toxicity are those of nicotinic cholinergic excess, most commonly including vomiting and agitation. Severe poisoning may cause seizures, cardiac dysrhythmias, hypotension, and neuromuscular blockade with respiratory failure from muscular paralysis.
- There are no antidotes for nicotine, and acute toxicity should be managed with symptom directed, supportive care.

86 PHENCYCLIDINE AND KETAMINE

Ruben E. Olmedo

Phencyclidine (PCP)

Ketamine

Dextromethorphan

HISTORY AND EPIDEMIOLOGY

Phencyclidine (PCP) was discovered in 1926 but was not developed as a general anesthetic until the 1950s. At that time, the Parke Davis drug company was searching for an ideal intravenous (IV) anesthetic to rapidly achieve analgesia and anesthesia with minimal cardiovascular and respiratory depression.³⁷ PCP was marketed under the name Sernyl because it rendered an apparent state of serenity when administered to laboratory monkeys. Its surgical use began in 1963, but was rapidly discontinued when a 10% to 30% incidence of postoperative psychoses and dysphoria was documented over the subsequent 2-year period.⁸⁶ By 1967 the use of PCP was limited exclusively to veterinary medicine as a tranquilizer marketed under the name Sernylan.

Simultaneously, in the 1960s, PCP emerged as a street drug in San Francisco called “the PeaCe Pill.”⁷⁰ Numerous street names have been given to phencyclidine; on the West Coast, it was called “angel dust,” PCP, “crystal,” and “crystal joints” (CJs); in Chicago it was called “THC” or “TAC”; and those on the East Coast opted for “the sheets,” “Hog,” or “elephant tranquilizer.”¹³² Ironically, PCP was initially unpopular with drug users because of its dysphoric effects and unpredictable oral absorption.¹⁷³ However, with time its use spread in a similar geographic pattern to that of marijuana and lysergic acid diethylamide (LSD), from the coastal United States to the Midwest region.⁷⁰

PCP abuse became widespread during the 1970s.^{26,200} The relatively easy and inexpensive synthesis coupled with the common marketing of PCP as LSD, mescaline, psilocybin, cocaine, amphetamine, and/or “synthetic THC” (tetrahydrocannabinol) added to its allure and consumption.¹³² By the late 1970s PCP abuse had reached epidemic proportions.⁸ The Drug Abuse Warning Network (DAWN) reported that the number of PCP-related emergencies and deaths had more than doubled from 1975 to 1977. In 1978 the National Institute of Drug Abuse reported that 13.9% of young adults (18–25 years old) had used PCP.⁵³ The manufacture of PCP was ultimately prohibited in 1978 when it was added to the list of federally controlled substances. Classifying PCP as a Schedule II drug led to its decrease in availability and, consequently, a decrease in its use. Although the 1980s brought about a cocaine epidemic that eclipsed PCP, PCP has remained consistently available, primarily regionalized to large cities in the northeastern United States and in the Los Angeles area,¹¹¹ where PCP use continues to rise and fall with societal trends. Because many of the PCP congeners made during the manufacturing process were being abused in place of PCP, the Controlled Substance Act of 1986 made these

derivatives illegal and established that the use of the precursor of PCP, piperidine, necessitated mandatory reporting. With this new law in place, those possessing similar but not identical illegal substances could be prosecuted. This led to a further decline in the popularity of PCP. Beginning in 1984, the overall use of PCP declined sharply, reaching a nadir in 1994.²⁰³ However, during the 8 years that followed, there was a small resurgence in reported PCP use, but never reaching the epidemic proportions of the 1970s. Peak use reached an annual prevalence rate of 2.6% in 1996 among 12th graders. DAWN reported that the highest number of PCP related emergencies occurred in Washington, DC, Philadelphia, Los Angeles, Chicago, and Newark, NJ.^{204,207,208} Since 2003, the use of PCP has declined and its prevalence has remained low. During these years the National Survey on Drug Use and Health reports that the annual prevalence rate for the use of PCP for young adults has fluctuated between 0.6% and 0.1% with the latest report of 0.3% in 2011. Lifetime prevalence use of PCP is highest among adults aged 23 to 30 years (3.3%).¹¹³

Laboratory investigation of phencyclidine derivatives led to the discovery of ketamine, a chloroketone analog. Ketamine was introduced for general clinical practice in 1970 and was marketed as Ketalar, Ketaject, and, for veterinary use, Ketavet. Because ketamine has approximately 5% to 10% of the potency of PCP and a much shorter duration of action, it provides greater control in clinical use. Thirty-five years of clinical experience have established that ketamine provides adequate surgical anesthesia, a rapid recovery, and less prominent emergence reactions than PCP.^{60,83,176,222} Because of the simplicity and efficacy of its use, it is regularly used in operating rooms, emergency departments (EDs), and throughout the developing world where little clinical monitoring is available during surgical and emergency procedures.^{57,82,83,85,86,177,221}

Abuse of ketamine was first noted on the West Coast in 1971.¹⁸⁹ During the 1980s there were reports of its abuse internationally, including physicians.^{4,72} The nonmedical use of dissociative anesthetics has continued to increase throughout the 1990s and into the 2000s, in spite of the common complications associated with their use.²⁰² Unfortunately, it is those same pharmacologic qualities that make ketamine more popular than PCP clinically that are responsible for its nonmedical popularity. Ketamine is regularly consumed at all-night “rave parties” and in nightclubs because of its “hallucinatory” and “out-of-body” effects, relatively inexpensive price, and short duration of effect: a single insufflation lasts between 15 and 20 minutes.^{12,47,100,104,223}

The use of ketamine is not limited to the inner city. In the past decade, the media reported police arrests in affluent suburban communities for possession and sale of ketamine, which is coupled to more in-depth and frequent reporting of its toxicity among users.^{47,100,174,223} By contrast to PCP, ketamine is not manufactured illegally, but rather, it is diverted from legitimate medical, dental, and veterinary sources. Additionally, with the advent of the Internet, its availability has dangerously grown nationwide; a sham “biotech” Internet company was seized by the New York City Police Department in 2000 for selling so-called date rape drugs, including ketamine.¹⁴⁵

Adverse reactions do occur, although there are few reports of fatalities secondary to ketamine, even during this period of increased use.^{76,122,126,151} Because of its abuse potential, ketamine was placed in Schedule III of the Controlled Substance Act in 1999.¹⁷⁶ DAWN reported that there was a more than 2000% increase of ketamine related ED visits between 1994 and 2001. Despite any clear reason, after peaking in 2001, there was a decline in ketamine related ED visits in 2002.²⁰⁵ The use of ketamine has remained very low since 2006,¹⁸⁸ with an annual prevalence rate at or below 1.3% for high school students and 0.8% for young adults.^{112,113,206}

PHARMACOLOGY

Chemistry

The chemical name, 1-(1-phenylcyclohexyl)piperidine, provided the basis for its street abbreviation, PCP. During its unlawful chemical synthesis, numerous analogs are made that have similar effects on the central nervous system (CNS) and have been used as PCP substitutes. These “designer” arylcyclohexylamines are aliphatic- or aromatic-substituted amines, ketones, or halides, and appear similar to the parent compound. More than 60 psychoactive analogs are known. The following salient points of the five most prevalent compounds are worth mentioning: 1-[1-(2-thienyl)cyclohexyl] piperidine (TCP) and 1-piperidino-cyclohexanecarbonitrile (PCC) are piperidine derivatives. Piperidine, the synthetic precursor, was formerly easily purchased for the manufacture of PCP and its derivatives. TCP, a thiophene analog, produces even more intense effects than PCP. An intermediate of PCP synthesis, PCC was a constituent of up to 22% of illicit xenobiotic preparations analyzed for phencyclidine. This most likely resulted from a poor manufacturing process.^{15,188} PCC degrades to piperidine, which is recognizable by its strong fishy odor. The presence of its carbonitrile group adds to its toxicity by generating cyanide when smoked.^{13,15,195,196} The pyrrolidine derivative, phencyclohexylpyrrolidine (PHP), is clinically comparable to PCP and is not detected by many of the available drug-screening methods.^{28,95} More potent than PCP, 1-phenyl-cyclohexylethylamine (PCE) was commonly available on the street as a white powder indistinguishable from PCP.¹⁸⁸ TCP, PCE, and PHP are classified as Schedule I drugs, and PCC is classified as Schedule II drug.

Ketamine and tiletamine, two legal analogs of PCP, are used clinically for sedation and anesthesia. In larger quantities, both are also used in veterinary medicine for animal sedation. Tiletamine, in combination with zolazepam (Telazol), is

commonly used for animal procedures in veterinary medicine. Ketamine is the only dissociative anesthetic product manufactured for human use for the purpose of anesthesia, conscious sedation, and the treatment of bronchospasm. The development of a mechanistic approach to pain therapy in the last 20 years has brought a renewed interest in the use of ketamine as an adjuvant to multimodal pain treatment. Ketamine is used prophylactically and therapeutically in children and adults in the management of postoperative pain. For the treatment of pain ketamine is administered intravenously (median dose: 0.4 mg/kg; range: 0.1–1.6), orally, intramuscularly, rectally, subcutaneously, intraarticularly, caudally, epidurally, transdermally, intranasally, or added to a patient-controlled analgesia device.^{65,87,96,117,179} Currently, the rapid antidepressant effect of ketamine is being studied clinically. A common single study dose of 0.5 mg/kg administered intravenously (IV) for 40 to 60 minutes to patients with refractory major depressive disorder provides a 14% to 70% antidepressant response lasting 72 hours postinfusion. Presently randomized control trials are underway to explore dosing, maintenance of response, mode of delivery, and adverse effects.¹

The molecular structure of ketamine [2-(ortho-chlorophenyl)-2-methylaminocyclohexanone] contains a chiral center, producing a racemic mixture of two resolvable optical isomers or enantiomers, the D(+)-isomer and L(–)-isomer. Commercially available preparations of ketamine contain equal concentrations of the two enantiomers. These two molecules differ in their pharmacodynamic effects. In a randomized, double-blind evaluation of patients undergoing surgery, the D(+)-isomer of ketamine was a more effective anesthetic but manifested a higher incidence of psychotic emergence reactions than the L(–)-isomer. In other studies, the D(+)-isomer caused a greater increase in both blood pressure and pulse than the L(–)-isomer, and also had more bronchodilatory effects.^{177,222}

Pharmacokinetics and Toxicokinetics

Phencyclidine is a white, stable solid readily soluble in both water and ethanol. It is a weak base with a pK_a between 8.6 and 9.4 and a high lipid-to-water-partition coefficient. It is rapidly absorbed from the respiratory and the gastrointestinal tracts; as such, it is typically self administered by oral ingestion, nasal insufflation, smoking, or intravenous and subcutaneous injection.

The effects of PCP are dependent on routes of delivery and dose. Its onset of action is most rapid from the IV and inhalational routes (2–5 minutes) and slowest (30–60 minutes) following gastrointestinal absorption.^{45,46} Sedation is commonly produced by doses of 0.25 mg intravenously, whereas oral ingestion typically requires 1 to 5 mg to produce similar sedation. Signs and symptoms of toxicity usually last 4 to 6 hours, and large overdoses generally resolve within 24 to 48 hours, but effects may persist in a chronic user.^{17,58,61,131,158,173} However, in the PCP-poisoned patient, the relationships between dose, clinical effects, and serum concentrations are not reliable or predictable.

There are several explanations for the protracted CNS effects of PCP. Its large volume of distribution of 6.2 L/kg^{45,229} and high lipid solubility account for its entry and storage in adipose and brain tissue. Also, on reaching the acidic cerebrospinal fluid (CSF), PCP becomes ionized, producing CSF concentrations approximately six to nine times greater than those of serum.¹⁴⁸

PCP undergoes first-order elimination over a wide range of doses. It has an apparent terminal half-life of 21 ± 3 hours under both control and overdose settings.^{45,103} Ninety percent of PCP is metabolized in the liver and 10% is excreted in the urine unchanged. PCP undergoes hepatic oxidative hydroxylation into two monohydroxylated and one dihydroxylated metabolites.⁴⁶ All three compounds are subsequently conjugated to form the more water-soluble glucuronide derivatives and then excreted in the urine.

Urine pH is an important determinant of renal elimination of PCP. In acidic urine, PCP becomes ionized and then cannot be reabsorbed. Acidification of the urine increased renal clearance of PCP from 1.98 ± 0.48 L/h to 2.4 ± 0.78 L/h.⁴⁵ If the urine pH is decreased to less than 5.0, then even higher renal clearance (8.04 ± 1.56 L/h) is noted.¹¹ Although this may account for a 23% increase in the renal clearance, it only represents a 1.1% increase of the total clearance.

Similarly, ketamine is water soluble but also has a high lipid solubility ($\text{Log } D = 2.01$) that enables it to distribute to the CNS readily. It has a pK_a of 7.5 and a volume of distribution of 1.8 ± 0.7 L/kg. Ketamine has approximately 10% of the potency of PCP.^{83,105} Human trials demonstrate that, similar to PCP, the clinical effects of ketamine are both route and dose dependent.^{49,52,60,197} Peak concentrations occur within 1 minute of IV administration and within 5 minutes of a 5 mg/kg intramuscular (IM) injection.^{222,233} Ketamine distributes immediately into the CNS with the duration of its hypnotic and anesthetic effects decreased by its redistribution from the brain to other tissues.²²² Recovery time averages 15 minutes for IV administration, but may require 30 to 120 minutes following IM administration. Oral or rectal doses are not well absorbed and undergo substantial first-pass metabolism.^{177,222} In contrast to oral administration of ketamine where effects last 4 to 8 hours, after nasal administration they last for 45 to 90 minutes.

Ketamine is extensively metabolized in the liver by the cytochrome P450 (CYP) isoenzyme CYP2B6 and to a lesser extent by CYP3A4 and CYP2C9.²³¹ Its biotransformation is complex with numerous metabolites described.^{3,177,222} The major pathway involves its N-demethylation to norketamine, a metabolite with one-third the anesthetic potency of ketamine.

Norketamine is hydroxylated at different sites within its hexanone ring, producing varying second chiral centers. Most of these diastereoisomers are glucuronidated to more water-soluble derivatives that are then excreted in the urine.^{83,177} Ketamine also undergoes ring hydroxylation prior to N-demethylation as a minor metabolic pathway. The elimination half-life, which reflects both metabolic and excretory phases, is 2.3 ± 0.5 hours and is prolonged when xenobiotics requiring hepatic metabolism are coadministered.¹²⁸ Because of the enzymatic metabolism, both tolerance and enzyme induction are reported following chronic administration.^{83,177}

Available Forms

PCP is available on the street in a variety of forms, including powder, liquid, tablets, leaf mixtures, and rock crystal. Because of its uncontrolled illegal manufacture, the contents of PCP vary considerably, with powder often the purest form. A typical dose consumed contains approximately 5 mg.¹⁷² Leaf mixtures are made by sprinkling approximately 1 to 10 mg of phencyclidine onto parsley, oregano, mint, tobacco, or marijuana. A typical PCP joint (known as “crystal joint,” “KJ,” or “supergrass”) is developed for smoking and contains about 1 mg per 150 mg of plant product.⁷ Mentholated cigarettes dipped into liquid PCP are known as “supercools.”

PCP is included in the US Federal Controlled Substance Act of 1970, reducing its availability for incorporation into marijuana cigarettes. There are reports of marijuana cigarettes being adulterated with PCP and sold on the street under varying names like “Illy” in Connecticut, “Hydro” in New York City, “Dip” in New Jersey, “Wet” in Philadelphia, and “Fry” in Texas.⁹⁸

The cigarettes are purportedly treated with “embalming fluid,” which allegedly enhances the euphoric effects of the drug. Rather, the embalming fluid, or another organic solvent, is used as a medium to allow a uniform distribution of PCP in these cigarettes.⁹⁸ Furthermore, the organic solvent may be the remnant of the organic solvent used in the synthesis of PCP or one of its analogs. In either case, the ability to smoke the cigarette prior to drying after dipping in the solvent/PCP (nonaqueous) mixture accounts for its various names. In most cases, this “enhanced” mixture appears to be purchased intentionally rather than having the PCP placed in these cigarettes surreptitiously.

On the street and on the Internet, ketamine is known as “vitamin K,” “Special K,” “Super K,” “Ket,” or simply “K.” It is available in a liquid form that is dried into a pure-white crystalline powder and is typically self-administered by ingestion or insufflation in a fashion similar to PCP. It is rarely injected IV or IM in aqueous form.

When used by injection, there is an observed demographic and behavioral difference among those who initiate drug injection use with ketamine and those who initiate injection use with another xenobiotic and later transition into ketamine injection.¹²⁵

Ketamine is primarily sold as tablets, capsules, or powder. These formulations are often adulterated with caffeine, methylenedioxymethamphetamine (MDMA), ephedrine, methamphetamine, heroin, and cocaine (a mixture known as CK or Calvin Klein).^{63,180} In fact, in addition to alcohol, MDMA (39%), heroin (17%), and cocaine (14%) are the most frequently mentioned xenobiotics used with ketamine.²¹¹ Exemplifying the commercial growth of ketamine, some of the tablets are even found to contain a “K” logo.⁶³ Common sedating doses are 75 to 300 mg orally (30–75 mg for insufflation). Higher doses, ranging between 300 and 450 mg orally (100–250 mg for insufflation), result in substantial CNS adverse effects. These manifestations are similar to the clinical “emergence reactions” that patients experience during ketamine anesthesia.

More recently, abuse of a ketamine analogue, methoxetamine (2-(3-methoxyphenyl)-2-(ethylamino) cyclohexanone) is reported. This designer drug is a means of evading drug enforcement. Sold through the Internet internationally as a white powder, it may be ingested, insufflated, or injected. Its market is mostly in the United Kingdom and is referred to by various names, including M-ket, Kmax, and Mexxy. Case reports indicate that the clinical symptoms of patients with methoxetamine toxicity are similar to those reported from ketamine.^{97,218,228}

PATHOPHYSIOLOGY

The arylcyclohexylamines, of which PCP and ketamine are prototypes, are a group of anesthetics that functionally and electrophysiologically “dissociate” the somatosensory cortex from higher centers.^{49,221} The precise mechanisms by which PCP and ketamine achieve these effects are complex and not fully understood; however, investigation of the nature of PCP-induced psychosis has led to a substantial identification of the various sites of PCP activity.

Most studies demonstrate that PCP and ketamine bind with high affinity to sites located in the cortex and limbic structures of the brain.¹³⁴ They block the NMDA receptors at serum concentrations encountered clinically.^{215,234} Analogs of PCP (TCP, PCE, PHP, and ketamine) and dizocilpine (MK-801) also interact with the NMDA receptor in a dose-response manner that corresponds appropriately to their neurobehavioral effect.^{27,185,224} These xenobiotics bind to the NMDA receptor at a site independent of glutamate.^{105,110,134,226} As such, they antagonize the action of glutamate on this channel and noncompetitively block Ca^{2+} influx (Fig. 14–14).

PCP and ketamine bind to the biogenic amine reuptake complex with 10% to 20% of the affinity to which they bind to the NMDA receptor. Binding occurs at physiologic concentrations that normally take place after subanesthetic doses.^{5,168} This weak inhibition of the catecholamine reuptake accounts for the respective sympathomimetic and psychomotor effects. An increase in blood pressure and heart rate is induced. Rapid IV infusion produces a more pronounced effect than by IM injection, with the D(+)-isomer having a greater effect than the L(-)-isomer.²²²

In significant overdoses, PCP and ketamine also stimulate sigma receptors at concentrations generally associated with coma, although with lower affinity than NMDA receptors.^{198,225} Both D₂ and sigma receptors have an inhibitory effect on the cholinergic receptor pathways.²²⁵ At the higher concentrations, typically associated with death, PCP and ketamine also bind to the nicotinic, opioid, and muscarinic cholinergic receptors.²¹⁴

NMDA antagonists produce effects on behavior, sensation, and cognition that resemble aspects of endogenous psychoses, particularly schizophrenia.^{106,165} These behavioral abnormalities were first observed in studies in the late 1950s when PCP, administered to healthy volunteers, generated a form of organic psychosis that mimicked schizophrenia. When PCP was administered to schizophrenic patients, it uniformly intensified their primary symptoms of profound disorganization, and some of these symptoms lasted for weeks.¹³¹ PCP psychosis is so similar to schizophrenia that many psychiatrists cannot distinguish them without a prior indication of drug abuse history.¹⁹⁴ The multireceptor action of PCP and its link to schizophrenia is made more intriguing as various antipsychotics (eg, phenothiazines, thioxanthenes, butyrophenones) are also α receptor agonists.⁸⁰

Current interest in the role of excitatory neurotransmitter systems in the pathophysiology of schizophrenia has led to similar observations in patients after ketamine administration. Subanesthetic doses of ketamine administered to both healthy and schizophrenic volunteers induced a mild, dose-related, short-lasting increase in psychotic symptoms. Although the normal and schizophrenic volunteers had different levels of baseline psychosis, the magnitude, time course, and dose-response changes in positive symptoms were similar across the two populations. Both groups experienced thought disorganization, such as concreteness and loose association, hallucinations, and delusions of varying intensity.^{120,122–124}

There is a connection between PCP psychosis and sensory processing. PCP and ketamine inhibit sensory perception in a dose-dependent manner. This processing in sensory information corresponds to their relative affinities to the NMDA receptor and not to the sigma receptor.^{7,168} Clinically, the impairment of sensory input produced by PCP resembles that of patients who are deprived of sensory stimulation.¹⁴¹ When external stimulation was reduced by environmental sensory deprivation, the psychotomimetic effects of PCP were diminished,⁴³ giving credence to the theory that it may not be anxiety that causes perceptual dysfunction in schizophrenia, but the converse.

Many of the NMDA antagonists, including PCP and ketamine, have a negative effect on cognition and memory. Repeated administration of PCP and ketamine in many animal models results in cognitive and memory impairment.^{93,108} Both impair concentration, recall, learning, and retention of new information.^{14,31,56,58,77,92–94,120,138,150,161} In human volunteers, ketamine selectively impairs explicit,⁷⁶ episodic,^{55,154} and procedural memory,¹⁵⁴ and disrupts frontal cortical function, as measured by the Wisconsin Card Sorting Task and verbal fluency,^{120,138} in a dose-dependent manner. Learning and memory impairments in volunteers who were administered subanesthetic doses of ketamine (0.65 mg/kg) are independent of the user's attention and related psychosis.¹³⁸ Testing performed on chronic ketamine users produces similar results that are long lasting and have more marked effects on semantic and episodic memory.^{55,56,156,157} Accordingly, it is presumed that the acute and repeated NMDA receptor antagonism interferes with those functions that integrate interoceptive and exteroceptive input in which goal-directed action becomes possible, similar to the organic psychosis in schizophrenia. Because the rapid antidepressant effects of ketamine have the potential for either continuous and/or repeated dosing, current research may attend to its long-term adverse effects.

Hypofunction of the NMDA receptor causes neuroanatomic and neurobehavioral effects. Animals exposed to NMDA antagonists such as PCP and dizocilpine transiently demonstrated neuronal vacuolar degeneration in the retrosplenial cortex and the posterior cingulate areas of the brain.^{163,164} The major function of cingulate cortical neurons is to mediate affective responses to pain.²¹⁶ Single high doses or repeated exposures to NMDA receptor antagonists are associated with a higher incidence of cellular death.^{48,66,67,163} This injury seems to be related to the induction of selective expression of individual heat shock proteins in this anatomical area.¹⁸⁷ Excitatory amino acids are neurotransmitters responsible for mediating seizure activity in the brain. Although NMDA inhibitors, the anticonvulsant properties of PCP and ketamine are not demonstrated. Animals administered PCP or PCP analogs progress through dose-related clonic activity followed by tonic-clonic convulsions, as is typical of classic convulsant compounds.¹⁶⁸ Animal research also demonstrates wide interspecies variability of the electroencephalographic (EEG) effects of PCP.⁶¹ In a murine seizure model, ketamine possessed selective anticonvulsant properties.³² In addition, ketamine preserves learning proficiency in rats when administered shortly after onset of status epilepticus, an effect that may prove useful in the clinical setting when combined with conventional antiepileptic medications.¹⁹⁹

In humans, although these dissociative xenobiotics induce excitatory activity in the thalamus and limbic areas, they do

not affect cortical regions.^{51,52,60,73} Excitation, muscle twitching, posturing,¹⁴⁹ and tonic–clonic motor activity with or without EEG changes are reported with these subcortical EEG alterations.^{35,50,73,149} In the clinical setting, many report ketamine to possess anticonvulsant properties at clinically relevant doses and may be explained by an NMDA inhibitory effect.^{35,50} This effect was employed to treat patients with refractory status epilepticus in the critical care setting.²¹⁰

The NMDA receptor is also responsible for the development of the neuronal organization of the central nervous system.^{101,102,190,191} It is linked to hypoxic–ischemic brain injury by mediating calcium influx, a final pathway in cell death. The uninhibited firing of NMDA afferent neurons secondary to brain injury causes their death, as well as the death of efferent neurons downstream. In neonatal rats, ketamine increases the rate of neuronal apoptosis.¹⁸⁵ NMDA antagonists such as PCP block hypoxic brain injury from stroke and trauma.^{18,130} In a rat model of ischemic stroke, PCP had a protective effect on the brain, demonstrated by a decreased rate of seizure activity.¹⁸ This effect is transient and has not been studied in humans.

PCP induces modest tolerance in rats and squirrel monkeys. The development of tolerance is mostly secondary to the pharmacologic effects of PCP rather than to biodispositional changes. Dependence was also observed in monkeys who self-administered PCP (10 mg/kg/d to serum concentrations of 100–300 ng/mL) over one month by the appearance of dramatic withdrawal signs when access was denied. Signs included vocalizations, bruxism, oculomotor hyperactivity, diarrhea, piloerection, difficulty remaining awake, tremors, and in one case convulsions.¹⁶ These signs appeared within 8 hours of abstinence and were most severe at about 24 hours. When either PCP or ketamine (2.5 mg/kg/h) was readministered to the animals, PCP withdrawal symptoms were reversed, indicating cross-dependence from PCP to ketamine.^{21,107,193}

Physiologic dependence in humans has not been formally studied. It is implied to occur by the observation that chronic PCP users developed depression, anxiety, irritability, lack of energy, sleep disturbance, and disturbed thoughts after one day of abstinence from drug use.¹⁷⁵ In addition, neonates whose mothers used PCP developed jitteriness, vomiting, and hypertonicity that lasted for at least 2 weeks.²⁰¹ These symptoms may represent PCP withdrawal or intrinsic teratogenic effects on neurologic development.^{81,101} Although there are no controlled studies observing the physiologic symptoms of withdrawal in humans who chronically use PCP or ketamine, there is a definite psychological dependence on the sensations experienced during recreational use of the drugs.¹⁸⁹ There are a few cases of ketamine tolerance where patients report a need to use an increased quantity of drug to get the same effect.^{54,152,169} In a study of ketamine abstinence, patients characterized their withdrawal symptoms as anxiety, shaking, sweating, and palpitations.¹⁵⁵ In addition, ketamine impairs response inhibition, which is found to be related to increases in subjective ratings of desire for the drug.¹⁵⁴

CLINICAL MANIFESTATIONS

The reported signs and symptoms of patients presenting to the ED with PCP and ketamine toxicity are variable. The variations are a result of differences in dosage, the multiple routes of administration, concomitant xenobiotic use, and other associated medical conditions. In accordance with their pharmacologic effect, ketamine toxicity produces signs and symptoms similar to PCP with a shorter duration of action. In addition, individual differences in xenobiotic susceptibility, the development of tolerance in chronic users, as well as contaminants in the drug manufacture, may account for erratic clinical findings.

Vital Signs

Body temperature is rarely affected directly by PCP and ketamine. In one large series, only 2.6% of patients demonstrated hyperthermia ($> 101.8^{\circ}\text{F}$ [38.8°C]).¹⁴² In an experimental animal model, PCP failed to increase body temperature.^{37,61} When hyperthermia does occur, all the known complications, including encephalopathy, rhabdomyolysis, myoglobinuria, acute kidney failure, electrolyte abnormalities, and liver failure, occur (Chap. 30).^{9,20,42,170}

Most PCP and ketamine toxic patients demonstrate mild sympathomimetic effects. PCP consistently increases both the systolic blood pressure (SBP) and diastolic blood pressure (DBP) in a dose-dependent fashion.^{37,61} Doses of 0.06 mg/kg of IV PCP increase the SBP and DBP by 8 mm Hg, whereas 0.25 mg/kg produce a 26 and 19 mm Hg increase in SBP and DBP, respectively. PCP also increases the heart rate, although it does so inconsistently.⁹⁰ Likewise, ketamine produces mild increases in blood pressure, heart rate, and cardiac output via this same mechanism.^{52,133,197,212,222} In fact, tachycardia was the most common finding on physical examination in a case series of ketamine abusers presenting to the ED.²²⁰

Cardiopulmonary

Cardiovascular catastrophes are rarely encountered in PCP toxicity.^{64,143} These complications may result from direct vasospasm,^{6,36} causing severe systemic hypertension, pulmonary edema, hypertensive encephalopathy,⁶⁵ and cerebral

hemorrhage.²³ Hypertension, along with abnormal behavior, miosis, and nystagmus in children, strongly suggest toxicity due to a dissociative anesthetic.¹¹⁵

The effect of PCP and ketamine on cardiac rhythm is controversial. Dysrhythmias are only observed in animals poisoned with very large doses of PCP. Ketamine both enhances and diminishes epinephrine-induced dysrhythmias in animals.^{22,62,91,116} The considerable experience in the use of ketamine anesthesia on humans undergoing surgery or cardiac catheterization has not demonstrated prodysrhythmic effects.^{69,159}

As these dissociative anesthetics were designed to maintain normal ventilation, hypoventilation is uncommon. In clinical studies, PCP increased the minute ventilation, tidal volume, and respiratory rate of volunteers.⁹⁰ Clinically, in PCP-toxic patients, irregular respiratory patterns develop as tachypnea much more often than as bradypnea.^{9,142} Hypoventilation, when present, is usually secondary to the use of particularly high doses of PCP. Acute respiratory distress syndrome secondary to respiratory depression is also a rare occurrence. Large doses of PCP (20 mg/kg) administered to laboratory animals produced respiratory depression.³⁷ Although respiratory depression in humans is an extremely rare event, it has been reported with fast or high-dose infusions of ketamine.^{84,222} In fact, ketamine has been successfully used to prevent intubation in patients with refractory asthma. Ketamine relaxes bronchial smooth muscles, decreases mean airway pressure and $P_{a_{CO_2}}$, and increases $P_{a_{O_2}}$.^{75,178,202,222}

Neuropsychiatric

Most patients with PCP and ketamine toxicity brought to medical attention manifest diverse psychomotor abnormalities.^{13,19,29,72,108,220} As dissociative anesthetics, these xenobiotics impair response to external stimuli by separating various elements of the mind. Consciousness, memory, perception, and motor activity appear dissociated from each other. This dissociation prevents the user from attaining cognition and properly assembling all this information to construct a reality. Clinically, the person may appear inebriated, either calm or agitated, and sometimes violent. In large overdoses, the anesthetic effect causes patients to develop stupor or coma. In recreational use, “dissociatives” are not taken for these effects, but rather for so-called out-of-body experiences. In addition patients often have disordered thought processes (including disorientation as to time, place, and person) or amnesia, paranoia, and dysphoria.⁷¹

The manifestations of PCP and ketamine toxicity are better illustrated by the results of their effects in controlled human studies. Volunteers who took oral doses of up to 7.5 mg/day of PCP or 0.1 mg/kg of ketamine exhibited clinical inebriation, but higher doses (PCP > 10 mg/day; ketamine 0.5 mg/kg) generally caused a more severe impairment of mental function.^{61,120} IV doses of 0.1 mg/kg of PCP^{17,58,131,158,181} and 0.5 mg/kg of ketamine^{120,168} cause diminution in all sensory modalities (pain, touch, proprioception, hearing, taste, and visual acuity) in a dose-dependent fashion. Both xenobiotics also cause feelings of apathy, depersonalization, hostility, isolation, and alterations in body image.^{17,58,74,109,137,156} The deficits in sensory modalities are evident prior to the development of the psychological effects of PCP, with pain perception disappearing first. This alteration in analgesic perception is caused by a blocking action on the thalamus and midbrain (Fig. 86–1).¹⁵⁸

FIGURE 86–1. Clinical effects of phencyclidine and ketamine. Phencyclidine and ketamine bind to different receptors in the CNS with varying degrees of affinity; ie, an increasing concentration is necessary to achieve the various clinical effects. ACh = acetylcholine; CNS = central nervous system; GABA = γ -aminobutyric acid; M = muscarinic receptor; MAOI = monoamine oxidase inhibitor; NMDA = N-methyl-d-aspartate; N_N = nicotinic receptor.

Abnormal stereognosis and proprioception occur in a dose-dependent manner. This disturbed perception results in body image distortions described as “numbness,” “sheer nothingness,” and “depersonalization.” The decrease of proprioceptive sensation to gravity probably gives the sensation of “tripping” or “flying.” Because all sensory modalities are affected, visual, auditory, and tactile illusions and delusions are common. Hallucinations are typically auditory rather than visual, which are more common with LSD use. The hallucinogenic effects of ketamine on healthy human volunteers are linearly related to steady-state concentrations between 50 and 200 ng/mL.²⁴ Most ketamine users report experiencing a “k-hole,” a slang term for the intense psychological and somatic state experienced while under the influence of ketamine. This experience varies with the individual, but can include buzzing, ringing or whistling sounds, traveling through a dark tunnel, intense visions, and out-of-body or near-death sensations.⁵⁹

The reaction to the misperceived or disconnected reality may result in unintentional actions and violent behavior. The hallmark of PCP toxicity is the recurring delusion of superhuman strength and invulnerability resulting from both its anesthetic and dissociative properties. There are case reports of patients presenting with trauma either from jumping from high altitudes, fighting large crowds or the police, or self-mutilation. The true extent and incidence of violence is probably less than previously suggested.²⁵

Typically, neurologic signs include horizontal, vertical, and/or rotatory nystagmus, ataxia, and altered gait. Initially, except for ataxia, motor movement is not impaired until the patient becomes unconscious. On physical examination, use of dissociative anesthetics typically produces relatively small pupils, nystagmus, and diplopia. In the largest case series reported to date, nystagmus and hypertension were noted in 57% of patients who had taken PCP.¹⁴² Smaller and more limited studies have found an incidence of nystagmus approximating 89%.¹⁹ In comparison, nystagmus was only found in 15% of patients with ketamine abuse.²⁰⁰ Other cerebellar manifestations were also encountered, most notably dizziness, ataxia, dysarthria, and nausea. A pooled data compilation of 35 reports demonstrated that emesis occurred 8.5% of the time.⁸⁴ In fact, Internet chat groups devoted to substance abuse commonly direct users to “mix dissociatives with marijuana” for its antiemetic effect.

Larger doses of PCP produce loss of balance and confusion, the latter characterized by inability to repeat a set of objects, frequent loss of ideas, blocking, lack of concreteness, and disordered linguistic expression.^{55,61,120,131,181} Similarly, ketamine users report a high incidence of incoordination, confusion, unusual thought content, and an inability to speak.⁵⁹ In general, dissociative anesthetics stimulate the CNS but seizures rarely occur, except at high doses. The largest case series of PCP-toxic patients detected a 3.1% incidence of seizures.¹⁴²

Although PCP and ketamine toxic patients also present with motor disturbances, it is unclear to what extent PCP and

ketamine are actually responsible for these manifestations. The most common of the reported disturbances are dystonic reactions: opisthotonos, torticollis, tortipelvis, and risus sardonius (facial grimacing). Myoclonic movements, tremor, hyperactivity, athetosis, stereotypies, and catalepsy also occur.^{13,30,72,142} A slight increase in muscle tone results from a dopaminergic effect.¹³¹ Laryngospasm requiring intubation has been reported after the use of ketamine anesthesia. The incidence of this complication is less than 0.017%.⁸³ By comparison, the incidence of laryngospasm following traditional general anesthesia is 2%.¹⁵⁰

Urological and Hepatobiliary

Intense abdominal and pelvic pain is regularly reported in habitual ketamine users.^{160,232} In the majority of cases, the etiology is urologic. The first case series describing ketamine-associated urological dysfunction was reported in 2007. The patients' symptoms consisted of severe lower urinary tract syndrome (LUTS): dysuria, frequency, urgency, urge incontinence, and painful hematuria (Fig. 86–2). When investigated by cystoscopy, patients with hematuria were frequently found to have ulcerative cystitis.¹⁸⁴

FIGURE 86–2. Ketamine-associated lower urinary tract syndrome. This abdominal-pelvic computed tomographic (CT) scan was obtained in an 18 year-old girl who presented to the hospital with complaints of severe abdominal pain and hematuria. The image demonstrates a small bladder volume with an irregular thickened mucosal surface that enhances with contrast. (Used with permission of The Division of Medical Toxicology, Department of Emergency Medicine, NYU School of Medicine, Bellevue Hospital Center.)

Subsequent reports have established LUTS as a complication in both recreational ketamine users as well as in a patient receiving ketamine therapeutically for chronic regional pain syndrome.^{39,89,103} The incidence of ketamine-induced urologic dysfunction is not well established. Studies from the United Kingdom report an incidence of 20%, whereas a study from Hong Kong reports the incidence of 32% and 92% in acute and chronic ketamine users respectively.^{139,227,232}

The symptoms of ketamine-induced urologic dysfunction are secondary to an inflammatory process that reduces bladder size. Initial urinalyses are typically sterile. Patients develop diminished voiding capacity of 20 to 200 mL, decreased bladder compliance, and detrusor overactivity as measured by urodynamic testing. A thickened bladder wall, a small bladder volume, and perivesicular stranding are usually detected by ultrasonography and computerized tomography (CT) of the lower urologic tract.¹³⁹ Cystoscopy demonstrates an erythematous bladder mucosa with various degrees of ulcerations. Bladder biopsies confer epithelium denudation and ulcerative cystitis. There is a marked lymphocytic infiltration with a variable number of eosinophils and fibrosis as well as squamous metaplasia and nephrogenic metaplasia. The exact mechanism by which ketamine or one of its metabolites causes the destruction of the urinary tract remains unknown.^{39,40,227,232}

The pathology of ketamine-induced urologic dysfunction is not confined to the lower urinary tract. Upper urinary tract involvement is variable. A lower incidence of 13% has been reported in the United Kingdom compared with 51% in Hong Kong. The lower incidence is thought to be due to patients in the United Kingdom seeking medical attention earlier than those living in Hong Kong. IV urography and urography by CT reveal unilateral or bilateral ureteric narrowing. Bilateral hydronephrosis was reported in 44% to 50% of patients, and renal impairment has also been described.^{139,147} Biopsy of the ureter in a patient who underwent right nephrectomy with an ileal conduit anastomosis to the left renal pelvis demonstrated nephrogenic metaplasia throughout the ureter extending to the renal pelvis as well as ulceration with associated inflammatory changes, as described the bladder biopsies.⁹⁹

Intense abdominal pain in frequent ketamine users is also suggested to be hepatobiliary in nature. Case series of patients who used ketamine illicitly or therapeutically report abnormal liver function tests and biliary tract abnormalities.^{129,162,183} CT revealed common bile duct dilation with a smooth tapered end, a condition that mimics benign cystic dilation of the bile ducts. Endoscopic retrograde cholangiopancreatography and hepatobiliary iminodiacetic acid studies concur with these findings, suggesting gallbladder wall dyskinesia. These biliary abnormalities are noted to subside with cessation of ketamine use.¹²⁸

Emergence Reaction

The acute psychosis observed during the recovery phase of PCP anesthesia limits its clinical use. This bizarre behavior, characterized by confusion, vivid dreaming, and hallucinations, is termed an “emergence reaction.” These reactions occur most frequently in middle-aged men, with a reported incidence of 17% to 30%.^{90,114} The most violent emergence reactions follow an IV dose of approximately 0.25 mg/kg of phencyclidine.⁶¹ The mildest degrees of agitation produced by PCP resemble the effects of ethanol intoxication.

These same postanesthetic reactions also limit the clinical use of ketamine. The incidence of emergence reactions following ketamine administration may approximate 50% in adults and 10% in children.⁸³ Patients older than 10 years of age, women, persons who normally dream frequently, have a prior personality disorder, or both, premorbid denial of presence of illness or anosognosia (denial of the presence of an illness), and paranoia incur the greatest risk.^{83,144} The incidence of the occurrence of emergence reactions appears to be exacerbated when dissociative anesthetics are rapidly IV administered, as well as in patients exposed to excessive stimuli during recovery. Although it has not been proved in a controlled study, reducing external stimuli during the recovery phase might reduce emergence reactions.

Ironically, the very characteristics thought to make PCP ideal for anesthesia—the preservation of muscle tone and cardiopulmonary function—magnify the difficulties in managing an individual who manifests dysphoria after an overdose. The course of delirium, stupor, and coma associated with PCP and ketamine is extremely variable, although the manifestations are much milder and shorter acting following ketamine use.

Cholinergic and Anticholinergic Effects

Both cholinergic and anticholinergic clinical manifestations occur in the PCP- or ketamine-toxic patient. Miosis or mydriasis, blurred vision, profuse diaphoresis, hypersalivation, bronchospasm, bronchorrhea, and urinary retention may occur.^{13,19,127,141,142} Clinically, ketamine stimulates salivary and tracheobronchial secretions, both of which are equally and effectively inhibited by atropine and glycopyrrolate.¹⁵² Furthermore, in a randomized, double-blind trial, after infusion of 1.5 mg/kg of ketamine in healthy volunteers, physostigmine decreased nystagmus, blurred vision, and the time to recovery. However, nausea and vomiting were more frequent.²¹¹

DIAGNOSTIC TESTING

If it is necessary to confirm the suspicion of PCP usage, then urine is most commonly used as a matrix for analysis, although serum, and possibly gastric contents, can also be used. Rarely is it essential to make this determination. Most hospital laboratories do not perform quantitative analysis of PCP, but many can perform a qualitative urine test for the presence of the drug. Qualitative testing is more important than a quantitative determination as serum concentrations do not correlate closely with the clinical effects. PCP is qualitatively detected by an enzyme immunoassay at a sensitivity of 10 ng/mL. High-affinity antibodies were once studied as specific PCP antagonists to reverse PCP-induced toxicity.^{167,213} Thus, the detection of PCP is dependent on the concentration of PCP in the body fluid tested and the affinity of the antibody for the PCP molecule. As such, the immunoassay antibody binding to a molecule similar to PCP can produce false-positive reactions. Metabolites of PCP, such as PCE, PHP, TCP, and its pyrrolizidine derivative TCPy, cross-react with the immunoassay at concentrations 30 times higher than those used to detect PCP. Because of its similar structure to PCP, dextromethorphan and its metabolite dextrorphan also cross-react with Syva enzyme-multiplied immunoassay and fluorescence polarization PCP assays (Chap. 6).^{100,219}

Although nonspecific, laboratory findings resulting from PCP use can include leukocytosis, hypoglycemia, and elevated

concentrations of muscle enzymes, myoglobin, BUN, and creatinine.¹⁴² The EEG reveals diffuse slowing with θ and δ waves, which may return to normal before the patient improves clinically.

There is no commercially available quantitative immunoassay for ketamine. When necessary, ketamine is detected by gas chromatography/mass spectroscopy. The increase in popularity in ketamine use in certain parts of the world has led to the development of rapid-detection urine assays that are sensitive, specific, and accurate.^{38,217} There is anecdotal evidence that ketamine also cross-reacts with the urine PCP immunoassay because of their structural similarity.¹⁸⁶ Other authors, including the manufacturer that tests the reactivity of the commercially available PCP immunoassay with ketamine, do not find such results.^{33,220}

MANAGEMENT

Agitation

Conservative management is indicated for PCP and ketamine toxicity and includes maintaining adequate respiration, circulation, and thermoregulation. The psychobehavioral symptoms observed during acute dissociative reactions and during the emergence reaction are similar. To treat the symptoms of agitation and alteration of mental status of acutely toxic PCP patients, it is helpful to recognize that both pharmacologic^{2,34,41,44,68,82,83,135,140} and behavioral^{43,44,83,121} modalities have been used to diminish agitation and emergence phenomena during conscious sedation with ketamine. To prevent self-injury, a common form of PCP-induced morbidity and mortality, the patient must be safely restrained, initially physically, and then chemically. An IV line should be inserted and blood drawn for electrolytes, glucose, BUN, and creatinine concentrations. The use of 0.5 to 1.0 g/kg of body weight of dextrose and 100 mg IV thiamine HCl should be considered as clinically indicated.

Although body temperature is directly affected by PCP and ketamine, hyperthermia may occur secondary to psychomotor agitation and should be rapidly identified. Treatment should be accomplished immediately with adequate sedation to control motor activity. At presentation, placing the patient in a quiet room with low sensory stimuli will help achieve this goal. Physical restraint should only be used temporarily, if necessary, until chemical sedation is achieved. Rapid immersion in an ice water bath may be necessary because body temperatures greater than 106°F (41.1°C) place the patient at a great risk for end-organ injury. These patients will need volume repletion and electrolyte supplementation because hyperthermia increases fluid loss from sweat.

In the pharmacologic treatment of emergence reactions, benzodiazepines have been used with great success. A benzodiazepine such as diazepam, administered in titrated doses of up to 10 mg intravenously every 5 to 10 minutes until agitation is controlled, is usually safe and effective. Numerous studies demonstrate the benefits of benzodiazepines, although under certain conditions^{41,83} they may prolong recovery time. Midazolam may be more effective than diazepam under certain circumstances.^{34,140} Additionally, in a double-blind placebo-controlled study, lorazepam reduced the anxiety associated with ketamine without antagonizing the cognitive or psychotomimetic effects of ketamine.¹¹⁹ By contrast, phenothiazines may lower the seizure threshold, and both phenothiazines and butyrophenones may cause acute dystonic reactions. Phenothiazines may also cause significant hypotension due to their α -adrenergic blocking effects on the vasculature, worsen hyperthermia, and exacerbate any anticholinergic effects from these drugs.

Some behavioral modalities have also been implemented in the treatment. Early studies demonstrated that the psychotomimetic effects of PCP were diminished when external stimulation was reduced by environmental sensory deprivation.⁴³ The practice of placing patients in a quiet room with minimal sensory stimulation is recommended by many, but has never been formally studied in a double-blind, controlled trial, nor is it functionally feasible in most clinical settings. Conversely, it is observed in patients undergoing ketamine anesthesia that emergence reactions are less violent when patients are talked to or when music is played.^{121,192}

Although it is always important to ask the patient the names, quantities, times, and route of all xenobiotics taken, the information obtained may be unreliable. Even when the patient is trying to cooperate and give an accurate history, many street psychoactive xenobiotics are mixtures whose contents are unknown to the patient. Consequently, pharmacologic management is complex and often sign or symptom dependent. Although some authors have attempted to define the appropriate therapy for specific PCP congeners and for ketamine-induced psychosis, no single approach has been consistently efficacious.^{77,78,118,136}

Cystitis

The objectives of the management of ketamine-induced cystitis are in making the diagnosis, decreasing symptoms and in maintaining kidney function. Urinalysis should be obtained on all symptomatic patients in order to exclude urinary tract infection and a serum creatinine should be obtained to evaluate kidney function. For patients whose symptoms are mild, abstinence from ketamine use may be sufficient to reverse symptoms and pathology. Several therapeutic regimens have been tried with little success. They include antibiotics, nonsteroidal antiinflammatory drugs (NSAIDs), steroids,

anticholinergics. Urologic evaluation and follow-up will be necessary.¹⁴⁷

Moderate and severe symptoms of LUTS are defined as a daytime frequency of more than six, nighttime frequency of one or more than one, regular urgency on voiding, and moderate bladder or pelvic pain. For those patients with these symptoms, urologic consultation and repeated kidney function monitoring are essential. Ultrasonography and urography by CT assist in detecting lower and upper tract abnormalities. Urodynamic studies may further quantify bladder voiding capacity and detrusor activity. Invasive procedures may need to be undertaken in patients with impaired kidney function and deterioration. Cystoscopy will aid in visualizing the bladder and excluding other causes of hematuria and LUTS. During this procedure, a bladder biopsy may be performed. Injury to the upper urologic tract may be imaged with urography by CT. Nephrostomy insertions may be necessary in patients who present with impaired kidney function secondary to ureteric narrowing. Refractory cases may need to undergo urinary diversion.^{40,99,139}

Decontamination

Patients with a history of recent oral use of PCP or ketamine are candidates for gastrointestinal decontamination. Although there is rarely, if ever, an indication for orogastric lavage, aggressive decontamination may be indicated if potentially lethal coingestants are suspected. Activated charcoal (1 g/kg) should be administered as soon as possible and may be repeated every 4 hours for several doses. Activated charcoal will effectively adsorb PCP and increase its nonrenal clearance; even without prior gastric evacuation this approach is usually adequate.¹⁷⁴

Theoretically, xenobiotics that are weak bases, such as PCP, can be eliminated more rapidly if the urine is acidified. Although urinary acidification with ammonium chloride was previously recommended,¹⁰ we do not recommend this approach. The risks associated with acidifying the urine—simultaneously inducing a systemic acidosis, thereby potentially increasing urinary myoglobin precipitation—outweigh any perceived benefits (Chap. 10).

As opposed to the problems in applying ion trapping to renal excretion, ion trapping results in the active mobilization of PCP into gastric secretions. PCP is in a substantially ionized (and therefore non-lipid-soluble) form in the acid of the stomach and can be absorbed only when it reaches the more alkaline intestine. As a result, gastric suction can remove a significant amount of the drug, as well as interrupt the gastroenteric circulation by which the xenobiotic is secreted into the acid environment of the stomach only to be reabsorbed again in the small intestine.¹⁰ However, continuous gastric suction is unnecessary and can also be dangerous. It should be considered only in comatose patients. Continuous suction may result in trauma to the patient as well as in fluid and electrolyte loss, which can further complicate management and possibly interfere with the efficacy of activated charcoal. For these reasons, the administration of single- or multiple-dose activated charcoal rather than continuous nasogastric suction appears to be the safest and most effective way of removing ion-trapped drug from the stomach in severely poisoned patients.

Most patients rapidly regain normal CNS function anywhere from 45 minutes to several hours after its use. However, those who have taken exceedingly high doses or who have an underlying psychiatric disorder may remain comatose or may exhibit bizarre behavior for days, or even weeks, before returning to normal. Those who rapidly regain normal function should be monitored for several hours and then, after a psychiatric consultation, should receive drug counseling and any additional social support available. Patients whose recovery is delayed should be treated supportively and monitored carefully in an intensive care unit.

Many patients become depressed and anxious during the “post-high” period, and chronic users may manifest a variety of psychiatric disturbances.²³⁰ These individuals typically present with repeated drug use, hospitalizations, and poor psychosocial functioning in the long term.

The major toxicity of PCP appears to be behaviorally related: self-inflicted injuries, injuries resulting from exceptional physical exertion, and injuries sustained as a result of resisting the application of physical restraints are frequent. Patients appear to be unaware of their surroundings and sometimes even oblivious to pain because of the dissociative anesthetic effects. In addition to major trauma, rhabdomyolysis and resultant myoglobinuric acute kidney injury account in large measure for the high morbidity and mortality associated with PCP intoxication. If significant rhabdomyolysis^{42,170} has occurred, early fluid therapy should be used to avoid deposition of myoglobin to the kidneys. Urinary alkalization as part of the treatment regimen for rhabdomyolysis would potentially increase PCP reabsorption and deposition in fat stores, but this is only theoretical.

Although the clinical experience with recreational use of ketamine is limited, toxic manifestations appear to be similar yet milder and shorter lived when compared with PCP. In a study of 20 patients who presented with acute ketamine toxicity, all were treated conservatively and successfully with intravenous hydration, and sedation with benzodiazepines.²²⁰

SUMMARY

- PCP and ketamine produce an “out-of-body experience” with seemingly hallucinatory effects.
- The action of these xenobiotics is largely mediated by the NMDA receptor.

- The neuropsychiatric toxicity is managed by supportive care.
- The popularity of ketamine may be related to its lesser toxicity and milder distortion of the personality.
- A chronic effect of ketamine abuse is cystitis and bladder dysfunction.

I. METALS

CASE STUDY 7

History A 45 year-old man presented to the hospital complaining of hand and foot pain so severe that he was unable to drive his car. The man had been well until several weeks earlier, when he began having gastrointestinal distress that he thought was “heartburn” and mild weight loss, which he attributed to his dyspepsia. He denied fever, chills, nausea, vomiting, or diarrhea. He also related that on the day prior to admission he was unable to eat a meal because he thought it was spoiled after taking a few bites. The next morning, while driving, he pulled off the road and phoned emergency medical services. He was taking no medications and had no allergies.

Physical Examination In the emergency department, the patient appeared well developed and well nourished, but was complaining of severe pain in his hands and feet. Vital signs were: blood pressure, 124/68 mm Hg; pulse, 92 beats/min; respiratory rate, 14 breaths/min; oral temperature, 98.6°F (37.0°C); oxygen saturation, 99% on room air; and a rapid reagent glucose of 128 mg/dL. Physical examination was notable for pupils that were equal, round (4 mm), and reactive to light; normal extraocular movements; and the absence of nuchal rigidity. His chest was clear to auscultation, and his heart sounds were normal. His abdomen was soft and nontender, with normal bowel sounds and no organomegaly. He was awake, alert, and oriented with normal symmetrical strength and brisk reflexes. Although he complained of pain in his hands and feet, his two-point discrimination, proprioception, and vibration sensation appeared normal. His gait was slightly wide based and slow, but this was thought to be secondary to pain. Cranial nerves II through XII appeared intact, and cerebellar testing was normal.

Immediate Assessment and Management Although the patient appeared uncomfortable, there was no perception of an immediate life threat. An intravenous line was inserted, and blood was obtained for a complete blood count, electrolytes, and liver function testing. A urinalysis was requested as was an electrocardiogram and a chest radiograph. Acetaminophen was given for analgesia, without relief. The patient required parenteral opioids to diminish his pain, although he noted that the distribution had spread to include most of his legs and arms. He also became somnolent, and it was unclear if the ensuing somnolence was opioid related.

What Is the Differential Diagnosis? The major presenting symptom in this case is a painful sensory peripheral neuropathy (an uncommon clinical manifestation) associated with gastrointestinal symptoms (a common manifestation). Considerations include a variety of metabolic and endocrine disorders, infections, medications, and toxins. Severely painful symmetrical paresthesias are fairly uncommon and the differential diagnosis is limited. Considerations include freezing injury such as frostbite ([Chap. 30](#)), proximity to radioactive materials ([Chap. 134](#)), and topical exposure to hydrofluoric acid ([Chap. 107](#)). A list of xenobiotics that can cause such findings following ingestion is found in ([Table CS7-1](#)).

What Immediate Diagnostic and Therapeutic Interventions Are Indicated? In addition to the above evaluation, a diagnosis of encephalitis was considered when the patient became somnolent, and a computed tomography (CT) scan of the head was obtained without intravenous contrast. A lumbar puncture was performed after the CT scan was interpreted as normal. The lumbar puncture showed: 2 red blood cells/mm³; 0 white blood cells/mm³; glucose, 85 mg/dL; and protein, 45 mg/dL.

Unfortunately, over the next 48 hours, the patient's condition deteriorated and was characterized by encephalopathy with cranial nerve dysfunction and weakness with loss of deep tendon reflexes. A repeat lumbar puncture demonstrated elevated protein without abnormal cells or findings on the Gram stain.

Further Diagnosis and Treatment A diagnosis of poisoning was considered, and a toxicology consult was obtained. The combination of gastrointestinal symptoms without significant diarrhea, severely painful ascending peripheral neuropathy and progression to encephalopathy with motor and cranial nerve findings strongly suggested metal poisoning, specifically thallium ([Chap. 102](#)). Treatment with Prussian Blue (Antidotes in Depth: A28) was recommended, and the original blood urine and cerebrospinal fluid were sent for thallium concentrations. Unfortunately, the patient's illness progressed rapidly, and he suffered a cardiac arrest shortly after the diagnosis was considered. Ultimately, a spot urine thallium concentration was reported as 50,000 µg/L (normal <5 µg/L), and his serum was 8700 µg/L (normal <2 µg/L).

Acknowledgment Postmortem findings and cerebrospinal fluid results of this case were reported in the following article: Sharma AN, Nelson LS, Hoffman RS: Cerebrospinal fluid analysis in fatal thallium poisoning: evidence for delayed distribution into the central nervous system. *Am J Forensic Med Pathol.* 2004;25:156–158.

87 ALUMINUM

Brenna M. Farmer

Aluminum (Al)

Atomic number	=	113
Atomic weight	=	26.98 Da
Normal concentrations		
Serum	<	2 µg/L (0.074 µmol/L)
Whole blood concentration	<	12 µg/L (4.43 µmol/L)
Urine (24 hour)	<	4–12 µg/g creatinine (1.48–4.45 µmol/g creatinine)

CHEMISTRY

Aluminum (Al) is the most abundant metal in the crust of the earth, where it is found in many types of ores: bauxite, gibbsite, boehmite, as alumina, and in gems such as ruby, sapphire, and turquoise. The most naturally occurring isotope is ²⁷Al. Aluminum is a nonessential element and a trace metal with a single oxidation state, Al³⁺.

The aluminum industry is one of the largest industries in the world. Aluminum ores are converted to alumina and then reduced to aluminum metal. The first step usually involves refining bauxite at high temperature and pressure in a caustic soda to form alumina (aluminum oxide, Al₂O₃). The second step occurs by a special method, the Hall-Heroult process, in potrooms and uses electrolytic reduction to form aluminum. Aluminum is then used alone or is processed into alloys to build a variety of products that are anticorrosive.¹⁶ Aluminum is found in cookware, infant formula,²¹ foil, vaccines as an adjuvant to boost immune response,²⁸ antiperspirants, antacids, and previously, in phosphate binders. It also contaminates hemodialysis (HD) fluids, intravenous (IV) fluids, total parenteral nutrition (TPN),³⁸ albumin,³⁹ and as alum solution (potassium aluminum sulfate or ammonium aluminum sulfate)—an astringent for bladder irrigation.⁹⁶ In this chapter, aluminum metal is discussed as an occupational toxin with mainly lung manifestations. Aluminum salts, the more common form discussed in aluminum toxicity, primarily act as neurotoxins, with both acute and chronic toxicity.

HISTORY AND EPIDEMIOLOGY

The first case of aluminum toxicity with neurologic findings was reported in 1921. This patient had memory loss, tremor, and impaired coordination.⁸⁶ Subsequently, a case series described occupational asthma in Norwegian aluminum (potroom) workers (“potroom asthma”).²² In 1947, 26% of German potroom workers exposed to high concentrations of aluminum dust mixed with mineral oil–based lubricants developed pulmonary fibrosis, “aluminosis”.²⁴ Some potroom workers also developed neurologic findings described as a progressive encephalopathy and termed “potroom palsy,” with balance problems, intention tremors, decreased cognitive ability, and impaired memory, initially described in 1962.^{45,51,71}

In the 1970s, encephalopathy in patients with chronic kidney disease (CKD) was attributed to using aluminum salt–containing phosphate binders or, more rarely, to aluminum contaminated dialysis fluid. This clinical syndrome, known as “dialysis dementia,” develop after years of HD.⁷⁷ By 1976, elevated serum aluminum concentrations were reported in encephalopathic HD patients.⁶⁶ Both the relationship between aluminum and microcytic anemia as well as the connection between aluminum and osteomalacia in dialysis patients were recognized in 1978.^{17,88}

In 1982, alum (potassium aluminum sulfate or ammonium aluminum sulfate) was first used in the treatment of hemorrhagic cystitis.⁶⁴ Neurotoxicity can develop if patients absorb alum systemically, especially if kidney insufficiency is present.

More recently, aluminum has been linked to the spongiform leukoencephalopathy that rarely develops in heroin abusers “chasing the dragon.” These patients inhale the pyrolysate of heroin heated on aluminum or tin foil. A 2007 study showed elevated urinary aluminum concentrations in patients using heroin in this manner.¹⁸ They then can develop bizarre behavior, slowed speech and movements, as well as cognitive abnormalities.⁴⁴

There is also a concern over the relationship between aluminum and Alzheimer disease. This linkage was studied because of the dialysis encephalopathy syndrome (dialysis dementia) and the association of aluminum with neuropsychiatric deficits and electroencephalographic (EEG) changes that occur in aluminum welders.⁷² Although aluminum is a component of neurofibrillary tangles in senile plaques associated with Alzheimer disease, to date no studies have proven that aluminum is the cause of the disease.^{56,66} Regardless, this association has led several agencies in the United States and Canada to decrease the amount of aluminum contamination allowable in food and water products.⁹²

ALUMINUM-CONTAINING XENOBIOTICS

Antacids

Aluminum-containing products are rarely prescribed. However, patients may take antacids containing aluminum hydroxide for symptomatic control of dyspepsia and gastroesophageal reflux disease. Aluminum hydroxide is usually packaged with magnesium hydroxide to counteract the induced delay of gastric emptying and constipation caused by aluminum hydroxide. These antacids are poorly absorbed and exit the stomach in about 30 minutes. The neutralizing effects of antacids last for 2 to 3 hours, especially in the presence of food.

Sucralfate

Sucralfate, an aluminum-containing salt with sucrose sulfate, is used for symptomatic control of ulcer disease, to accelerate healing of peptic ulcer disease, and as a protectant against stress ulcer formation. This sucrose aluminum complex is poorly absorbed from the gastrointestinal (GI) tract, and the little that is absorbed is excreted by the kidney without undergoing any metabolic changes. Although not approved by the US Food and Drug Administration as a phosphate binder, it does have phosphate binding properties.⁹

Alum

Alum is usually a potassium aluminum sulfate salt $[KAl(SO_4)_2 \cdot 12H_2O]$ or an ammonium aluminum sulfate salt $[NH_4Al(SO_4)_2 \cdot 12H_2O]$, as a 1% solution, and is typically used as an astringent during bladder irrigation for hemorrhagic cystitis, although use is rare. It is poorly absorbed unless there is a defect in the bladder wall.

TOXICOKINETICS

Aluminum toxicokinetics are difficult to comprehend as many mechanisms have not been elucidated. It is known that daily intake occurs, that absorption is limited, but that the concentrations of aluminum in urine and feces do not equal 100% of the intake.²⁵ More research is necessary to determine the full extent of toxicokinetics.

Absorption

Aluminum is ubiquitous in the food we eat and water we drink.⁶⁵ The daily intake of aluminum in the United States is estimated to be 2 to 25 mg from food and beverages, depending on the diet studied.²⁵ GI absorption mainly occurs in the proximal small bowel with uptake by the intestinal mucosal cells. Uptake occurs through both passive transport methods such as diffusion and active transport methods via transferrin as well as active methods shared by calcium.²⁵ Transferrin may also mediate absorption into the blood from the mucosal cells.²⁵ The exact amount of aluminum absorption in humans is difficult to quantify due to the short half-lives of isotopes and lack of sensitive analysis techniques.²⁵ However, GI absorption increases in the presence of citrate, other small organic acids, and in uremia, based on increases in serum aluminum concentrations.^{25,29,62,83} The GI absorption of aluminum is decreased in the presence of phosphorus and silicon.²⁹ There is negligible dermal absorption from the use of antiperspirants containing aluminum.^{19,25} Pulmonary absorption of inhaled aluminum particulates is 1.5% to 2%, based on increased urinary aluminum excretion in workers exposed to aluminum containing metal fumes.^{25,57,81}

Distribution

The initial distribution of aluminum is consistent with blood volume 0.06 L/kg with equal distribution between plasma and red blood cells in the blood.⁸⁹ Aluminum then becomes 90% bound to transferrin, with approximately 10% bound to citrate.^{87,91} From the blood, it distributes to many tissues, including 50% to the bone, where it is concentrated at the mineralization front,⁹⁵ and approximately 1% to the brain, primarily in the gray matter.⁶⁶ The remainder of the aluminum appears to distribute variably to the heart, liver, kidney, and other organ systems. The primary carrier in the cerebrospinal fluid (CSF) is citrate.⁹¹ Intracellularly, aluminum localizes in the lysosomes of brain neurons, liver (not the Kupffer cells),

spleen, kidney epithelial tubules and glomerular mesangium cells, cardiac myocytes,^{5,75} and in the mitochondria of osteoblasts.¹⁵

Metabolism/Excretion

Aluminum is not metabolized in the body and is considered to be greater than 95% excreted unchanged in the urine with a normal daily urinary excretion of less than 50 µg.²⁵ Citrate in the blood may enhance the excretion of aluminum.⁴⁸ Less than 2% of aluminum is excreted by the bile.^{40,69,93} Because of the primary renal excretion of aluminum, patients with severe CKD have decreased aluminum excretion. The elimination half-life for aluminum is approximately 85 days in dialysis patients.⁷⁶ Based on urinary excretion in workers (with preserved kidney function) with prolonged occupational exposure, the apparent half-life is extended to years.⁴³ This prolonged half-life may be related to deposits of aluminum metal dust in the lungs of those workers (such as in those patients with pulmonary fibrosis from exposure to the aluminum dust). There is no normal reference point for elimination half-life.

PATHOPHYSIOLOGY

Little is known about the pathophysiology of aluminum toxicity. The information that follows is based on a summary of limited research. Some animal studies provide insight into mechanisms that may be responsible for the toxicity of aluminum, but the studies should not be considered to form a comprehensive understanding of aluminum toxicity as the basic science studies raise more questions. There remain many gaps in our knowledge of aluminum toxicity for different organ systems.

Pulmonary System

In rats exposed to alumina and aluminum through intratracheal injection, fibrosis develops.^{35,36} These animals develop epithelialization of alveoli, with focal fibrosis occurring in the respiratory bronchioles and alveolar ducts with alveolar proteinosis.^{27,68}

Central Nervous System

Aluminum is associated with acute encephalopathy, dialysis encephalopathy, seizures, and Alzheimer disease. The primary site of aluminum entry into the brain appears to be the cerebral microvasculature. Following IV administration in rats and rabbits, aluminum concentrations are higher in the frontal cortex than in the lateral ventricles. The cortex concentrations should result from blood supply, while lateral ventricle concentration may represent blood supply or be CSF derived as the lateral ventricles are bathed in CSF.^{94,95} The mechanisms of entry are postulated to be transferrin mediated, endocytosis and other active processes.²² Aluminum interacts with the acetylcholine pathways in the brain and decreases acetylcholine activity. It decreases the amount of high-affinity choline uptake in the brains of rats and also decreases the activity of choline acetyltransferase in rabbit brains.^{30,42} Rabbits treated with aluminum have significantly decreased acetylcholine outflow compared with controls; this does not improve with potassium addition to the neurons. This finding suggests that aluminum may attenuate the response of neurons to potassium-induced depolarization.⁹⁴ Adult rabbits exposed to aluminum also have a significant reduction in conditioned responses compared with rabbits exposed in utero or in the first or second month postpartum.

Hematologic System

Prior to alterations in the central nervous system, aluminum affects hematopoiesis. A microcytic hypochromic anemia results. In rats, aluminum inhibits cell growth, while in humans hematopoietic cells are inhibited. In mice, aluminum decreases cell proliferation and hemoglobin synthesis.^{3,55} It inhibits δ-aminolevulinic acid dehydrogenase in the heme synthesis pathway,^{1,52} leading to the accumulation of erythrocyte protoporphyrins (Fig. 22–3). This effect is most noted in HD patients with aluminum overload.¹⁰

Musculoskeletal System

Vitamin D resistant osteomalacia and osteopathy occurs in patients with aluminum toxicity. It is characterized by hyperosteoidosis, minimal osteoblastic activity, and decreased mineralization. The metabolism and kinetics of calcium, magnesium, and phosphate do not appear to be affected in these patients.¹³ Aluminum concentrates in the mitochondria of the osteoblasts at the mineralization front.¹⁵ It is theorized that aluminum competes and replaces other cations in the bone, leading to osteopathy.²⁶ The osteomalacia is not caused solely by CKD but develops in the presence of aluminum exposure.⁷³ In rat studies, exogenous parathyroid hormone enhanced aluminum deposition into bone, leading to

osteopathy.^{49,50}

MANIFESTATIONS

Acute Toxicity

Regardless of etiology, patients with acute aluminum toxicity develop encephalopathy, myoclonus, and seizures. The encephalopathy manifests as disorientation, confusion, and coma. All symptoms appear to develop within days to a few weeks of receiving massive systemic aluminum exposure (usually to an aluminum salt). Serum concentrations range from barely elevated to extremely elevated. Most patients who manifest toxicity have systemically absorbed aluminum, usually in the presence of CKD. In several case reports of acute aluminum toxicity, the initial exposure to aluminum was associated with alum bladder irrigations for hemorrhagic cystitis.^{34,59,67} In two patients, these symptoms developed after only weeks of exposure to aluminum containing phosphate binders in the presence of citrate.³⁷ Two neonates with uremia developed neurotoxicity after exposure over a 1 to 2 month period to infant formula with high aluminum content.²⁰ Recovery occurs in patients treated with deferoxamine and or HD.^{34,58,59} Patients in whom aluminum toxicity is not recognized and or treated late usually die (despite supportive care in the intensive care unit, never recovering a normal mental status).^{37,77,80}

Chronic Toxicity

Two distinct types of chronic aluminum toxicity are reported: occupationally related lung problems, such as asthma and pulmonary fibrosis, and a multisystem syndrome most often noted in HD patients, which was initially described as dialysis encephalopathy syndrome or “dialysis dementia.” As these names only describe one organ system involvement, they should not be used.

Pulmonary. Potroom asthma consists of dyspnea, cough, wheezing, bronchitis, and chest tightness.⁵³ These symptoms may present after only a few months of exposure to the metal fumes of aluminum and aluminum dust. The asthma may improve upon cessation of work in the potroom, although some workers never fully improve.⁶³ These symptoms may be a cause for high turnover in potroom workers and appear to have made long-term follow-up difficult.^{32,85}

Pulmonary fibrosis from aluminum, termed aluminosis, is very similar to the other pneumoconiosis, like silicosis, and appears to progress in a similar manner. This manifestation develops in workers exposed to aluminum dust. Patients experience cough, shortness of breath, and dyspnea on exertion, and they eventually develop restrictive lung disease.^{41,54} Abnormal chest radiograph findings include increased pulmonary markings, distortion of pleura and diaphragms, and irregular opacities.^{23,30,78} Recovery of lung function does not occur, and several patients have died from complications of pulmonary disease such as pneumonia.

Multisystem Toxicity. The other form of chronic aluminum toxicity has multisystem manifestations. It primarily affects three organ systems: hematopoietic, nervous, and musculoskeletal. In patients with CKD, the toxicity appears to occur after months to years of exposure to aluminum salt–contaminated dialysate and or aluminum salt–containing phosphate binders such as aluminum hydroxide and sucralfate. A similar presentation has been reported in a patient using aluminum-coated cookware to boil methadone for IV abuse. The patient experienced 3 months of chronic aluminum toxicity (prior to presentation) after 4 years of processing his methadone this way.^{21,96} Three industrial workers exposed to aluminum metal powder were reported to have encephalopathy. One of these workers had a brain aluminum concentration 20 times normal.⁴⁵ One infant with kidney insufficiency developed focal seizures, which eventually progressed to generalized seizures, hypotonia, poor head control, ataxia, and developmental delay in the presence of elevated serum aluminum concentration after 10 months of exposure to aluminum salt–containing phosphate binders.⁷⁰

The microcytic hypochromic anemia of aluminum poisoning is unresponsive to iron replacement therapy.³¹ This clinical finding usually precedes encephalopathy and osteomalacia.⁷⁹ The encephalopathy is characterized by speech disturbances, EEG abnormalities, myoclonic jerks, and dementia.⁸⁴ The typical speech disturbances include dyspraxia, dysphasia, stuttering, and possibly mutism.^{46,74,84} EEG abnormalities include slowing of the normal rhythm and high voltage biphasic or triphasic spikes.^{47,84} The myoclonic activity can include uncontrolled twitching movements, myoclonus, or seizures.⁸⁴ The osteopathy and osteomalacia can lead to bone pain and fractures.^{14,92} Death is common in these patients when aluminum toxicity is not recognized and treated.

DIAGNOSTIC TESTS

A normal serum aluminum concentration should be less than or equal to 2 µg/L,²⁵ while a whole blood aluminum concentration should be less than 12 µg/L.⁸² Daily urinary excretion less than 50 µg aluminum is considered normal.^{25,61} Toxicity has occurred in a wide range of serum and urine concentrations, with patients dying who had severe manifestations

and concentrations only slightly above normal.

Pulmonary function testing can be performed to evaluate for restrictive lung function, as occurs with aluminosis.

MANAGEMENT

Patients should be removed from any aluminum exposure if identified. Exposure to aluminum in industry and exposure to antacids containing aluminum salts should also be limited. Patients with occupational asthma from aluminum exposure should be symptomatically treated with bronchodilators and steroids.

The only chelator with proven benefit is deferoxamine (DFO). Chelation therapy is recommended for both acute and chronic toxicity from aluminum salts. Chelation appears to limit and improve manifestations of neurotoxicity, anemia, and osteomalacia (Antidotes in Depth: A7). Other chelators such as D-penicillamine and 2,3-dimercapto-1-propanol (BAL) have been tried in chronic HD patients without any improvement in their manifestations or aluminum concentrations.¹² A review of numerous chelator studies revealed that no other chelator has been found as an alternative to DFO.⁹⁰

Acute Toxicity

A DFO dose of 15 mg/kg/d intravenously is recommended. Adults have received doses ranging from 1 to 2 g for aluminum toxicity. DFO chelates the aluminum to form aluminoxamine, which is excreted in the urine or removed by HD.⁹¹ Chelation mobilizes aluminum from its storage sites in blood and increases its renal elimination.

In patients with stage 5 CKD, chelation therapy is usually followed 6 to 8 hours later by HD with a high-flux membrane in order to clear the aluminoxamine (the aluminum-DFO product).⁵⁸ Patients with normal kidney function may not require HD, as the aluminoxamine is excreted in the urine.

Chronic Toxicity

Chelation therapy with DFO reverses encephalopathy, osteomalacia, and anemia. Numerous case reports demonstrate the reversal of the neurotoxicity, vitamin D-resistant bone disease, and iron-resistant anemia.^{4,8,11} The National Kidney Foundation has issued complicated guidelines for the treatment of dialysis encephalopathy. It consists of 4 months of once weekly DFO 5 mg/kg over 1 hour given 5 hours before a regularly scheduled HD session in patients with an aluminum concentration greater than 300 µg/L. In patients with aluminum concentrations between 50 and 300 µg/L, DFO 5 mg/kg is given the last hour of HD, once a week for 2 months. Serum aluminum concentrations are then monitored, and this therapy is repeated as needed.⁶⁰ Recent studies have evaluated the effect of lower doses of DFO (2.5 mg/kg/week) for treatment of chronic toxicity in dialysis patients.³³

SUMMARY

- Inhalational exposure to aluminum metal causes pulmonary toxicity, primarily manifested as bronchospasm, but progresses to restrictive lung disease.
- Acutely, aluminum salts are neurotoxins with manifestations of encephalopathy and seizures.
- Chronically, aluminum salts affect at least three systems with manifestations of anemia, encephalopathy, dementia, and osteomalacia.
- Treatment involves limiting or terminating exposure, chelation with DFO, and HD in patients with CKD.

88 ANTIMONY

Asim F. Tarabar

Antimony (Sb)

Atomic number	=	51
Atomic weight	=	121.75 Da
Normal concentrations		
Serum	<	3 µg/L (24.6 nmol/L)
Urine (24 hour)	<	6.2 µg/L (50.1 nmol/L)
	<	3.5 µg/g creatinine (28.7 nmol/g creatinine)

HISTORY AND EPIDEMIOLOGY

Antimony (Sb) and its compounds are among the oldest known remedies in the practice of medicine.^{102,154} Because of a strong chemical similarity to arsenic, the features of antimony poisoning closely resemble arsenic poisoning (Chap. 89). Antimony poisoning also shares features common with other metal poisonings in the chapters that follow. Although relatively uncommon, antimony toxicity still occurs, usually as a complication of the treatment of visceral leishmaniasis.⁹² Acute overdose represents an even more rare, but potentially lethal event, often as a result of a nonconventional alcohol aversion treatment.^{99,139}

Objects discovered during exploration of ancient Mesopotamian life (third and fourth millennium B.C.) suggested that both the Sumerians and the Chaldeans were able to produce pure antimony.^{102,154} The reference to eye paint in the Old Testament suggested the use of antimony.¹⁰² For several thousand years, Asian and Middle Eastern countries used antimony sulfide in the production of cosmetics, including rouge and black paint for eyebrows, also known as kohl or surma.^{97,103} Because of the scarcity of antimony sulfide, lead replaced antimony as a main component in more modern cosmetic preparations.

One of the first monographs on metals, written in the 16th century, included a description of antimony.¹⁴⁶ The medicinal use of antimony for the treatment of syphilis, whooping cough, and gout dates to the medieval period. Paracelsus was credited with establishing antimony compounds as therapeutic agents and increasing their popularity. In spite of being aware of its toxic potential, many of the disciples of Paracelsus enthusiastically continued the use of antimony.¹⁰² Various antimony compounds were also used as topical preparations for the treatment of herpes, leprosy, mania, and epilepsy.¹⁵⁴ Orally administered tartar emetic (antimony potassium tartrate) was used for treatment of fever, pneumonia, inflammatory conditions, and as a decongestant, emetic, and sedative, but it was abandoned because of its significant toxicity.^{22,47,66,81} The use of antimony as a homicidal agent¹⁴⁰ continued well into the 20th century (Chap. 1).

The current medical use of antimony is limited to the treatments of leishmaniasis and schistosomiasis, and to sporadic use as aversive therapy for substance abuse.^{99,139} Pentavalent compounds are used because they are better tolerated. In the endemic regions of the world, generic pentavalent antimonials remain the mainstay of therapy because of their efficacy and low cost; however, the growing incidence of resistance may reduce future use.¹⁰⁷

Some contemporary homeopathic⁶⁰ and anthroposophical¹³³ practices still recommend use of antimonial compounds as home remedies; however, these practices are rare.^{102,154} In spite of its anticancer effects in vitro⁴⁷ and remarkable therapeutic efficacy in patients with acute promyelocytic leukemia,¹²⁹ there is no current accepted oncologic use of antimony. When compared to suramin, a well-known antineoplastic compound, sodium stibogluconate appears to be a better inhibitor, giving a foundation for future research of antimony-based antineoplastics.¹²⁹

The elemental form of antimony has very few industrial uses because of its physical limitations, particularly the fact that it is not malleable. In contrast, its alloys with copper, lead, and tin have important applications. Various antimony compounds can be used in the production of textiles, enamels, ceramics, fireworks, and pigments, and as catalysts in chemical reactions. Industrial and occupational exposure to antimony occurs mainly by the inhalation of dust or fumes during the processing or packaging of antimony compounds.^{14,71} Smelters can have occupational exposure to antimony as it

is often present in arsenic-containing ore.⁵⁹ A time-weighted average over an 8 hour shift of permissible exposure limit for antimony and its compounds is established at 0.5 mg per cubic meter of air (mg/m^3) by the Occupational Safety and Health Administration.¹⁴⁵ Antimony concentrations in cigarette smoke range from 10 to 60 mg/kg ,^{59,110} which may be responsible for a substantial percentage of antimony found in the lungs of smokers.⁵⁹

In developed countries, antimony poisoning rarely occurs following intentional ingestion of antimony preparations.^{99,154} Most recent descriptions of antimony toxicity result from parenteral exposures during the treatment of schistosomiasis and leishmaniasis. Because of the infrequent use of therapeutic antimony preparations, health care providers in the United States may not be familiar with the standard dosing and administration procedures, placing their patients at risk for therapeutic misadventures.⁸⁷ One can expect an increase in cases of domestically treated leishmaniasis as a result of deployment of US troops to the Middle East.¹⁵⁵

Oral exposures usually occur following the use of antimony potassium tartrate-containing compounds.^{99,139} Several cases were described after the use of old porcelain houseware or after use of antimony compounds as home remedies.^{4,90,106,139}

CHEMISTRY

Antimony is located in the same group on the periodic table as arsenic (As), and as such it has many similar chemical, physical, and toxicologic properties. Because it can react as both a metal and a nonmetal, antimony is classified as a metalloid (Chap. 12).^{14,135} Pure antimony is a lustrous, silver-white, brittle, hard metal that is easily pulverized.^{105,154} It is extremely rare to find elemental antimony in nature because of its ability to rapidly convert to either antimony oxide or antimony trioxide.¹⁴ It has been suggested that even its name originates from anti monon (enmity to solitude) because antimony is almost always found with some other metal.¹⁰² Thus, for the purposes of this chapter, the term antimony refers to antimony ions.

In nature, antimony can be found in more than 100 different minerals,^{83,102} including stibnite, cervantite, valentine, and kermesite.⁵³ The sulfide ore (stibnite) is the most abundant form,¹⁰² and Bolivia and South Africa are among the leading producers.¹⁵⁴ Like arsenic, antimony forms both organic and inorganic compounds with trivalent (3^+) and pentavalent (5^+) oxidation states. Common inorganic trivalent antimony compounds include antimony potassium tartrate ($\text{C}_8\text{H}_4\text{K}_2\text{O}_{12}\text{Sb}_2$), antimony trichloride (SbCl_3), antimony trioxide (Sb_2O_3), antimony trisulfide (Sb_2S_3), and stibine (SbH_3). Antimony pentasulfide (Sb_2S_5) and pentoxide (Sb_2O_5) are inorganic compounds that can act as oxidizing agents.⁶⁸ Antimony pentachloride (SbCl_5) is used as a chemical reagent with acidic properties. It reacts with water, forming hydrochloric acid that causes a direct corrosive effect on skin and mucous membranes.³⁷

Standard treatment of cutaneous leishmaniasis, recommended by the World Health Organization (WHO) and the Centers for Disease Control (CDC), is a 20 day course of 20 $\text{mg}/\text{kg}/\text{d}$ of sodium stibogluconate.¹⁵⁵ Use of higher doses is associated with more side effects.¹⁵⁵ A recent new analytical approach measured a higher presence of trivalent antimony than previously reported in the pentavalent antimonial drug, suggesting that the pentavalent form acts as a carrier. It is postulated that trivalent antimony is released specifically in the acidic intracellular compartment targeting the Leishmania parasites. Released trivalent antimony could be responsible for the toxic effects of antiparasitic treatment.¹²⁸ The proposed mechanism of antimonial activity against the Leishmania parasites is inhibition of trypanothione reductase that is essential for the parasite survival and virulence.⁸

From an industrial perspective, the most important application of antimony is the use of antimony oxychloride ($\text{Sb}_2\text{O}_3\text{Cl}_2$) as a flame retardant.¹⁰² Investigation by the CDC of a possible antimony toxicity outbreak in US firefighters concluded that wearing uniforms made from fabric that contains antimony is safe.²⁹

Analysis of soil around firing ranges⁹⁵ and environmental examination around mines revealed elevated concentrations of antimony that can pose significant health risk.^{70,157} A public health concern was raised after reports of elevated antimony concentrations in water containers and commercial juices due to leaching from the packaging material or flawed manufacturing process.^{67,130}

Tartar emetic (antimony potassium tartrate) is an odorless trivalent antimony compound with a sweet metallic taste⁶⁹ and a potent emetic effect.⁶⁸ Antimony potassium tartrate is considered to be one of the most toxic antimony compounds, with minimal lethal doses reported between 200 mg ¹⁰⁶ and 1200 mg .¹⁰² There are large species variations of the LD_{50} in experimental animals, with a reported range of 115 mg/kg in rabbits and rats to 600 mg/kg in mice. In comparison, because of low water solubility, antimony trioxide is considered to be nontoxic, with an LD_{50} greater than 20,000 mg/kg .⁵⁷

PHARMACOLOGY

The antiparasitic mechanisms action of antimony may result from the inhibition of phosphofructokinase, which is the rate-limiting step in the glycolytic pathway of schistosoma.³¹ Trivalent antimony compounds inhibit phosphofructokinase, leading to energy failure from impaired adenosine triphosphate (ATP) synthesis.^{27,154} It is speculated that antimonial preparations exert their antiparasitic effect through selective targeting of guanosine diphosphate–mannose pyrophosphorylase, which interferes with nucleoside and mannose metabolism.⁵⁴ The result is that the parasites cannot synthesize purines and cannot survive without these mannose-containing glycoconjugates. The most recently proposed mechanism involves inhibition of trypanothione reductase.⁸ Even less is known about the effects of antimony in humans. It has been proposed that, like other metals, antimony inactivates thiol containing proteins and enzymes by binding to sulfhydryl groups.⁴² Pentavalent antimony may act as a prodrug that is converted in acidic intracellular compartment into active and more toxic trivalent antimony.¹²⁸

TOXICOKINETICS

Absorption

Antimony is absorbed by inhalation, ingestion, or transcutaneously. Absorption from the gastrointestinal tract begins immediately following ingestion, and the oral bioavailability of antimony ranges from 15% to 50%.^{58,147} It is suggested that antimony absorption might be a saturable process, given that several studies failed to demonstrate a dose-response relationship for absorption.^{2,136} In fact, after a lethal ingestion of antimony tartrate, the total body antimony burden was only 5% of the ingested dose.⁹⁶ This poor gastrointestinal absorption in humans, in addition to the concomitant emesis, necessitates parenteral administration of many antimony based pharmaceuticals.

Pulmonary absorption of many inorganic antimony compounds is very slow and limited by low solubility.¹⁰² In contrast, animal data suggest that inhaled trivalent antimony is well absorbed from the lung, distributed to various organs, and subsequently excreted in the feces and urine.⁴⁶

Transcutaneous absorption of antimony trioxide and pentoxide was documented in studies with rabbits,¹⁰⁹ however, dermal absorption in humans of antimony trioxide is considered negligible.¹²⁵ The CDC, in its investigation of possible outbreak of antimony exposure in firefighters, did not measure significant transcutaneous absorption from the antimony containing uniforms.²⁹

Distribution

Distribution depends on the oxidation state of antimony. In animals, more than 95% of trivalent antimony is incorporated into the red blood cells within 2 hours of exposure, whereas in a similar time frame, 90% of pentavalent antimony remains in the serum.⁴⁸

When administered intravenously or orally, antimony is predominantly distributed among highly vascular organs, including the liver, kidneys, thyroid, and adrenals.^{115,154} The antimony that is detected in the liver and spleen is predominantly in the pentavalent form, whereas the thyroid accumulates trivalent forms.¹³ Uptake by the liver occurs through the mechanisms of diffusion and saturable binding.¹³² In a hamster model, following a single injection of organic antimonials, the greatest concentration of antimony was found in the liver.⁵⁸ After inhalation, antimony accumulates predominantly in red blood cells and to a significantly lesser extent in liver and spleen.^{46,48} It is possible that inhaled antimony is retained in the lungs for a prolonged period of time without significant systemic absorption and distribution.⁵⁹ Animal data also reported accumulation of antimony in the skeletal system and in fur.^{50,51}

After intramuscular (IM) administration of sodium stibogluconate, the antimony concentration time profile suggested the two-compartment open model, with rapid distribution phase and slower elimination half-life in the range of 10 hours.¹⁵⁹

Metabolism

Although antimony and arsenic share many toxicokinetic properties, unlike arsenic, inorganic trivalent antimony is not methylated in vivo.⁷ Some microorganisms, however, are capable of biomethylation of antimony.¹⁷ Instead, in humans, antimony is converted by binding to macromolecules, by incorporation into lipids,¹⁶ and by covalent interactions with sulfhydryl groups and phosphates. Pentavalent antimony may be converted to trivalent compounds in the liver¹⁵⁴ or it can release trivalent form into acidic intracellular environment of Leishmania infected cells.¹²⁸

Excretion

Trivalent antimony is excreted in the bile after conjugation with glutathione. A significant proportion of excreted antimony undergoes enterohepatic recirculation.⁷ The remainder is excreted in urine. The overall elimination is very slow, with only 10% of a given dose cleared in the first 24 hours and 30% in the first week;¹¹ some urinary antimony is still detected in the urine 100 days after administration.^{98,154} Pentavalent antimony is much more rapidly excreted by the kidneys than trivalent antimony (50%–60% versus 10% over the first 24 hours).¹⁵⁴ In actuality, renal excretion of sodium stibogluconate can be as high as 90% within 6 hours of an IM administration.¹²² However, urine and serum antimony concentrations remain elevated for several years following therapeutic use.¹⁰¹ In workers, urine concentrations of pentavalent antimony correlate well with the extent of exposure.⁷

The clearance of tartar emetic has a biphasic pattern, with 90% being excreted within 24 hours after acute exposure, followed by a second slower phase with an estimated half-life of approximately 16 days.⁵⁰

The renal elimination half-life of inhaled stibine was estimated at approximately 4 days following occupational exposure.⁹¹

PATHOPHYSIOLOGY

Antimony has no known biological functions and is considered to be potentially toxic even at very low concentrations.¹³¹ Like other toxic metals, antimony binds to sulfhydryl groups to inhibit a variety of metabolic functions.^{32,42} Trivalent antimony compounds are more toxic than the pentavalent compounds because of their higher affinity for erythrocytes and sulfhydryl groups.⁹³ Tartar emetic and other antimony salts are also considered gastrointestinal irritants. One proposed mechanism for this local effect is the activation of enterochromaffin cells, which produce and secrete serotonin (5-HT₃). Released serotonin acts on the 5-HT₃ receptors, stimulating vagal sensory fibers and activating the vomiting center.^{65,149} In addition, there is apparent direct central medullary action, particularly after administration of higher doses of antimony.¹⁵⁴

CLINICAL MANIFESTATIONS

Data on human toxicity of antimony are very limited. They are largely extrapolated from occupationally exposed patients, adverse effects that have occurred during treatment of leishmaniasis and schistosomiasis, and very few case reports of intentional antimony exposures.¹⁰⁶ Serious adverse events and deaths resulting from the treatment with sodium stibogluconate are very rare, and if they occur, they are most often resulting from cardiac dysrhythmias or pancreatitis.¹⁵⁵ Patients older than 50 years may be at increased risk for more serious reactions to meglumine antimonate used for the treatment of visceral leishmaniasis.^{45,112}

Workers with occupational exposures usually present with subtle clinical symptoms as chronic toxicity develops slowly over time. It is important to recognize that antimony ore contains a small concentration of arsenic, making it difficult to determine whether the effects on workers are caused by contaminants such as arsenic or by the antimony. Therapeutic side effects of antiparasitic treatment may have acute and subacute clinical manifestations, as some patients with leishmaniasis require prolonged antimonial treatment to achieve cure,¹⁴³ exposing them, over time, to very large cumulative doses. Therapeutic misadventures are possible, particularly in the setting where antimony preparations are rarely used and health care providers are not familiar with the dosing regimen.⁸⁶

Patients with acute ingestions usually present with symptoms mimicking the toxicity of arsenic and other metal and metalloid salts.

Local Irritation

The most common manifestations of antimony toxicity involve local irritation. In sufficient concentration, antimony acts as an irritant to the eyes, skin, and mucosa. Ophthalmic exposure can cause conjunctivitis.^{19,53,123} Irritation of the upper respiratory tract can lead to pharyngitis and frequent epistaxis.¹⁵²

Antimony pentachloride is very irritating and can cause local dermal and mucosal burns. It reacts with water, releasing hydrochloric acid, heat, and antimony pentoxide (Sb₂O₅). Following ingestion, contact with the water in saliva produces sufficient hydrochloric acid with the potential to result in consequential gastrointestinal burns.

Ocular exposure to Sb₂O₅ can cause typical caustic injury, resulting in blepharospasm, lacrimation, photophobia, and even corneal burns. Exposure to antimony trichloride fumes can cause similar ocular symptoms.⁶¹

Following systemic exposure ocular toxicity can manifest in optic atrophy, uveitis, and retinal hemorrhage with exudates resulting with diminished visual acuity.^{34,89} Some of these changes can be permanent.⁸⁹

Thrombophlebitis is common after intravenous (IV) use of antimony but is also reported when poisoning occurs

orally.⁹⁶

Gastrointestinal. Following acute exposures, antimony can rapidly produce anorexia, nausea, vomiting, abdominal pain, and diarrhea.^{96,99,150} Some patients may report a metallic taste in the mouth.^{7,40} It is possible to sense a garlic odor on the breath, but this might be due to concomitant arsenic exposure. In severe overdose, gastrointestinal irritation can progress to hemorrhagic gastritis.⁹⁶ Workers chronically exposed to antimony dusts have a much higher incidence of gastrointestinal ulcers in comparison to controls (63 per 1000 versus 15 per 1000).²³ Many patients develop pancreatitis following treatment with pentavalent antimonial salts.^{41,56,104} Because most cases improved despite continuation of treatment, a mechanism other than direct pancreatic toxicity is presumed. In another series, several patients with human immunodeficiency virus (HIV) who were treated with high doses of meglumine antimonate developed severe pancreatitis and died.⁴³

Cardiovascular. In animals, antimony decreases myocardial contraction; lowers coronary vasomotor tone, producing decreased systolic pressure; and causes bradycardia.^{39,154} The majority of reported human cardiac effects are related to the electrocardiographic (ECG) changes. Prolongation of the QT interval, inversion or flattening of T waves, and ST segment changes are frequently described during treatment of visceral leishmaniasis with pentavalent antimonial compounds (sodium stibogluconate and meglumine antimonate).^{33,126,153} Torsade de pointes was described in patients treated with pentavalent antimonial preparations.^{114,142} Prolongation of the cardiac action potential may be due to an increase in cardiac calcium currents.⁹⁴

In patients with underlying myocardial disease such as a cardiomyopathy, ECG changes can occur even at subtherapeutic antimony doses.⁶⁴ These changes are not necessarily associated with deterioration in cardiac function.^{73,75} However, it is important to recognize that pentavalent antimonial drugs used for the treatment of leishmaniasis are associated with sudden death, probably as a result of the development of ventricular dysrhythmias.^{30,138} Cardiomyopathy followed by congestive heart failure and death is rare but is a reported adverse effect attributed to antimony.^{112,137} Pericarditis can present with chest pain and typical ECG changes during the treatment with antimony.⁴⁹

In regard to chronic antimony exposure, it appears that elevated concentrations of antimony in urine are associated with an increase in composite cardiovascular and cerebrovascular disease.¹

Respiratory. Local irritation from antimony trioxide can produce laryngitis, tracheitis, and pneumonitis.^{59,123,141} Pneumonitis is usually reversible after exposure ceases and can be followed radiologically.¹²³ Acute respiratory distress syndrome was reported after acute exposure to antimony pentachloride.^{37,38}

Although antimony oxides are capable of causing metal fume fever,^{6,52} this is much less common in comparison to exposure to zinc oxide (**Chaps. 103 and 124**).^{6,52} Antimony metal fume fever is reported to occur even with air concentrations below 5 mg/m³.³⁶

Workers chronically exposed to antimony compounds for many years may develop “antimony pneumoconiosis.”^{35,103} Patients present with cough, wheezing, and exertional dyspnea that can progress to obstructive lung disease. Radiologically, antimony pneumoconiosis appears as diffuse, dense, punctate nonconfluent opacities with a predominant distribution in middle and lower lung lobes with or without pleural adhesions.¹¹⁹

Renal. Patients treated with sodium stibogluconate can develop varied manifestations of nephrotoxicity ranging from renal cell casts, proteinuria, and increased blood urea nitrogen concentration³⁴ to acute kidney injury (AKI).^{9,121} Some patients can also develop renal tubular acidosis⁸⁰ and acute tubular necrosis.¹²⁰ Older age and underlying chronic kidney disease are risk factors for development of AKI that can progress to death.¹¹² Hemodialysis may be helpful during oliguric phase in acute overdose.⁹⁹

Hepatic. Acute exposure to antimony can result in severe acute liver injury.⁹⁹ Chronic therapeutic use of antimony compounds for the treatment of leishmaniasis can cause liver toxicity that can range from reversible elevations of aminotransferase concentrations to hepatic necrosis.^{76,78,127,154} Elderly patients are at an increased risk for development of significant hepatic failure.¹¹² Pediatric patients treated for leishmaniasis may develop fulminant hepatic failure after an initial positive response to antimony. The mechanism is unknown, but may be due to a direct antimony effect in combination with immunologically mediated liver injury.^{10,44}

Hematologic. Severe anemia was reported in HIV positive patients during treatment with sodium stibogluconate. Bone marrow biopsy documented transient severe marrow dyserythropoiesis, followed by complete recovery on discontinuation of the therapy.^{77,100}

Patients treated with sodium stibogluconate for visceral leishmaniasis occasionally develop thrombocytopenia.^{20,74,86} Rare cases of epistaxis are described during the treatment, and it is unclear if they are associated with thrombocytopenia.⁸⁸ Visceral leishmaniasis itself is known to be associated with pancytopenia, probably as a result of increased destruction of peripheral blood cells.¹¹⁸ It may be difficult to determine whether this phenomenon is caused by disease itself or is

secondary to the treatment, although some authors suggested a drug-induced immune thrombocytopenia.¹¹⁸

Leukopenia is frequently observed in patients treated with antimonial compounds.^{43,154,156} Some authors speculate that antimony-induced lymphopenia is associated with an increased frequency of herpes zoster in HIV infected patients.¹⁵⁶ It is suggested that pentavalent antimony can theoretically precipitate sickle cell crisis via common glutathione pathway.⁵⁵ A study with homeopathic antimony indicated procoagulant effect, and even some homeopathic practitioners use it in the treatment of bleeding disorder.⁷⁹

Dermatologic. Antimony spots¹³⁴ are papules and pustules that develop around sweat and sebaceous glands and may resemble varicella. Chronically exposed patients can develop areas of eczema and lichenification that typically occur in the summer and are usually found on the arms, legs, and in the joint creases with sparing of the face, hands, and feet.^{103,123} A similar skin rash was described in the 18th century after external application of antimony tartrate for medicinal use.¹⁰² Interestingly, these eruptions were usually interpreted as a sign of cure.⁶⁶ It is also suggested that antimony trioxide can cause contact dermatitis.¹⁰⁸ A very high incidence of severe cutaneous reactions (37%) was reported in patients who were treated with meglumine antimonate at 20 mg/kg/d.¹¹³ This high incidence was associated with high concentrations of other metals in the one particular drug lot. Herpes zoster was reported as a complication of antileishmaniasis treatment and it may be resulting from leukopenia.^{113,156}

Neurologic. A patient with cutaneous leishmaniasis who was treated with sodium stibogluconate (pentavalent antimony) developed a reversible, peripheral sensory neuropathy in temporal association with treatment.²⁵

Musculoskeletal. Therapeutic use of parenteral antimonials can be associated with diffuse muscle and joint pain.^{28,40,127,154} One of the most frequently reported clinical adverse effects of pentavalent antimonials was musculoskeletal pain.¹¹³ The symptoms can be so severe that they will require treatment interruption in about one third of the patients. Patients that are not candidates for the treatment with nonsteroidal antiinflammatory drug treatment can be managed with glucocorticoids.²⁴

Reproductive. In animal studies, antimony causes ovarian atrophy, uterine metaplasia, and impaired conception.¹⁵ An association between spontaneous abortion and premature births reported in women who were occupationally exposed to antimony salts. Antimony was found in the blood, urine, placenta, amniotic fluid, and breast milk of these women.¹⁵

Carcinogenicity. Female rats developed lung tumors after inhalation of antimony trioxide and antimony trisulfide.^{18,63,148} A survey among antimony smelters suggested an excess of lung cancer, with a latency of 20 years, in comparison to a nonexposed population. However, concomitant exposure to arsenic and its effects could not be excluded, and the data were poorly or inadequately controlled for smoking habits.⁸⁵ In one group of workers who were exposed to antimony oxide over 9 to 31 years, there was no increased incidence of lung cancer.¹¹⁹ Patients with schistosomiasis have an increased incidence of bladder tumors, and antimony compounds are considered to be one potential cause.¹⁵⁴ The International Agency for Research on Cancer classified antimony trioxide as possibly carcinogenic to humans (group 2B).⁶²

Genotoxicity. Both stibine and trimethylstibine are capable of damaging DNA, presumably by the generation of reactive oxygen species. Other forms of antimony tested, including potassium antimony tartrate, potassium hexahydroxyantimonate, and trimethylantimony dichloride, were found to not be genotoxic.⁵ Trivalent antimony interferes with proteins involved in nucleotide excision repair and partly impairs this pathway, pointing to an indirect mechanism in the genotoxicity of trivalent antimony.⁶²

STIBINE

Antimony compounds can react with nascent hydrogen, forming an extremely toxic gas, stibine (SbH_3), which resembles arsine (AsH_3) (Chap. 89). Stibine is probably the most toxic antimony compound. It is a colorless gas with a very unpleasant smell that rapidly decomposes at temperatures above 302°F (150°C).^{72,154} Historically, stibine release was reported during charging of lead storage batteries.¹⁵⁴ In addition to gastrointestinal symptoms that include nausea, vomiting, and abdominal pain, stibine has strong oxidative properties that may result in massive hemolysis (Chap. 22). Similar to arsine,¹²⁴ severe stibine exposure may result in hematuria, rhabdomyolysis, and death. Maintenance workers are advised to avoid use of drain cleaners containing sodium hydroxide, which is capable of releasing hydrogen in situations where antimony may be present.¹¹⁶

DIAGNOSTIC TESTING

Standard laboratory testing to help identify volume depletion and AKI is indicated for patients with acute antimony toxicity. A complete blood count, electrolytes, renal function studies, and a urinalysis should be obtained. When there is a known or suspected exposure to stibine, additional studies should include tests for hemolysis, such as determinations of bilirubin and

haptoglobin. Blood should also be obtained for a blood type and cross-match, as transfusions are likely to be required.

An ECG should be obtained to evaluate for QT interval prolongation and dysrhythmias. Patients with known myocardial disease should have frequent evaluations of cardiac function,⁶⁴ and continuous ECG monitoring is recommended for all patients with significant symptoms or abnormal cardiovascular status. A chest radiograph should be performed in patients with respiratory symptoms and evidence of hypoxia after significant inhalation exposure. In addition, an abdominal radiograph should be considered in patients with ingestion to evaluate gastrointestinal antimony load and help guide decontamination.²⁶

Antimony concentration in a 24-hour urine collection can be used for assessment of the intensity of exposure to either trivalent or pentavalent antimony.⁷ A normal urinary antimony concentration in nonexposed patients is reported in the range of < 6.2 µg/L.^{117,151} A serum antimony concentration cannot be determined in a timely fashion. The normal serum concentration of antimony is in the range of < 3 µg/L,¹⁰¹ although some laboratories use higher values.¹¹¹

TREATMENT

Decontamination

Following a significant acute ingestion, the majority of patients develop vomiting. Induction of emesis is unlikely to offer any additional benefit. In contrast, gastric lavage may be beneficial, especially if performed before the onset of spontaneous emesis. Although it is unknown whether antimony is adsorbed to activated charcoal, based on experience with salts of arsenic, thallium, and mercury, administration of activated charcoal is appropriate. Additionally, because antimony has a documented enterohepatic circulation, multiple-dose activated charcoal may be of value.⁷ Limited data on arsenic decontamination suggested effectiveness of this method.⁸⁴ Based on experience with arsenic poisoning, the whole bowel irrigation (WBI) should be attempted in severe ingestions in patients who are able to tolerate it, especially if radiographs confirm radiopaque material.^{3,26} One author suggested that WBI has no effectiveness after 48 hours from arsenic exposure.⁸⁴

For patients exposed to stibine, removal from the exposure should be followed by the administration of high-flow oxygen. Theoretically, patients with severe stibine exposures may require exchange transfusion for removal of the stibine–hemoglobin complex.¹²⁴ Dermal exposures, particularly to antimony tri- or pentachloride, may require decontamination with soap and water. Prompt removal from the contaminated area is important for patients exposed to stibine. Rescuers need to take appropriate precautions to ensure their own safety ([Chap. 131](#)).

Supportive Care

The mainstay of treatment for antimony poisoning is good supportive care. Clinicians should anticipate massive volume depletion and begin rehydration with isotonic crystalloid solutions. Electrolytes, urine output, and renal and liver function⁹⁹ should be followed closely. A central venous pressure monitor may be required in patients with cardiovascular instability. Antiemetics are indicated both for patient comfort and to facilitate the administration of activated charcoal. Following stibine exposure, the hemoglobin concentration should be followed closely and blood should be transfused based on standard criteria.

Chelation

Human experience with regard to chelation of antimony is rather limited because of the scarcity of serious toxicity and the rarity of instances when patients have received chelation. Most of the available data are based on animal experimentation. Dimercaprol, succimer, and dimercaptopropane–sulfonic acid (DMPS) all improve survival of experimental animals.^{12,21,82,144} A group from Shanghai demonstrated the ability of the sodium salt of succimer to increase the murine LD₅₀ of tartar emetic 16-fold.¹⁵⁸ One animal study that compared survival after treatment with multiple chelators concluded that the most effective antidotes were DMPS and succimer.¹²

A single case series documented survival in three of four patients exposed to tartar emetic who were treated with intramuscular dimercaprol at a dose of 200 to 600 mg/d. All four patients had increased urinary excretion of antimony.⁹⁶ In another case report, a patient survived after chelation with dimercaprol but without evidence of enhanced urinary excretion of antimony.⁷ Although specific recommendations are difficult to make, it is reasonable to begin therapy with IM dimercaprol until it is certain that antimony is removed from the gastrointestinal tract, at which time the patient can be switched to oral succimer. If the patient experiences cardiac or respiratory symptoms with associated ECG changes during administration of dimercaprol, treatment should be stopped.⁹⁹ Because chelation doses for antimony poisoning are not established, chelators should be administered in doses and regimens that are determined to be safe and effective for other metals (Antidotes in Depth: A25 and A26).

SUMMARY

- Antimony toxicity should be suspected in patients with unexplained profuse nausea, vomiting, diarrhea, and abdominal pain, particularly in the setting of alcohol aversion treatment.
- Most of the patients will require only supportive therapy with decontamination.
- Multiple doses of activated charcoal should be administered.
- WBI should be administered in the first 48 hours following oral exposure.
- Symptomatic patients should be admitted to telemetry for monitoring for cardiac dysrhythmias.
- Chelation should be considered in severe cases of acute overdose.
- Serious complications from treatment of leishmaniasis antimonial preparations are rare; they are mostly related to the heart and pancreas, with age and underlying diseases constituting known risk factors.

89 ARSENIC

Stephen W. Munday

Arsenic (As)

Atomic number = 33

Atomic weight = 74.92 Da

Normal concentrations

Whole blood < 5 µg/L (0.067 µmol/L)

Urine (24 hour) < 50 µg/L (0.67 µmol/L)

< 1.33 µmol/g creatinine (13.3 µmol/g creatinine)

HISTORY AND EPIDEMIOLOGY

Arsenic poisoning can be unintentional, suicidal, homicidal, occupational, environmental, or iatrogenic.^{108,109,141,165} Mass poisonings have occurred. Nearly 400 residents of Hong Kong fell ill after eating contaminated bread from the Esing Bakery in 1857; two bakery foremen were thought to have tampered with the recipe.⁸⁹ The 1900 Staffordshire beer epidemic in England saw 6000 beer drinkers fall ill and 70 die from beer brewed with sugar made with arsenic-contaminated sulfuric acid.¹⁰⁸ In Wakayama, Japan, 67 people were poisoned by eating intentionally contaminated curry at a festival in 1998.²²³ In 2003, the largest recent outbreak of arsenic poisoning in the United States occurred in New Sweden, Maine, when intentionally adulterated church coffee resulted in the death of one parishioner and the hospitalization of an additional 15 victims.¹⁹ Arsenic trioxide (As₂O₃) reemerged as a treatment for acute promyelocytic leukemia (APML) in the 1990s after physicians in Harbin, China, found a high remission rate in patients given, a crude As₂O₃ infusion.^{126,259}

Contaminated soil, water, and food are the primary sources of arsenic for the general population. Pentavalent arsenic (As⁵⁺) is the most common inorganic form in the environment.⁵⁷ Inorganic arsenic exposure from food is generally low and usually occurs from soil-derived foods such as rice and produce.^{32,199,250,258} Exposure to organic arsenic compounds of low toxicity occurs from consumption of algae, fish, and shellfish. In the past two decades, consumption of contaminated water has emerged as the primary cause of large-scale outbreaks of chronic arsenic toxicity. Arsenic leaches from certain minerals and ores, as well as from industrial waste.¹⁴⁸ In Bangladesh, millions of people have been poisoned by drinking water from wells contaminated with arsenic leached from ground minerals.¹⁷⁰ Ironically, the wells were dug to obtain safer groundwater. Hydroarsenicism is also reported in Chile, Taiwan, Brazil, India, Mexico, and Argentina.^{35,51,57,102,148,170,239} In 2001, the US Environmental Protection Agency decreased the maximum contaminant concentration of arsenic in drinking water to 10 parts per billion (ppb), or 10 µg/L, after statistical modeling indicated an increased risk of lung and bladder cancer from water contaminated with arsenic at the formerly acceptable concentration of 50 ppb.⁶⁶ The World Health Organization also recommends a maximum concentration of 10 ppb.

CHEMISTRY

Arsenic is a metalloid that exists in multiple forms: elemental, gaseous (arsine), organic, and inorganic [As³⁺ (trivalent, or arsenite) and As⁵⁺ (pentavalent, or arsenate)]. Tables 89–1 and 89–2 list sources of arsenic and regulatory standards about arsenic, respectively. Arsenic metal is considered nonpoisonous because of its insolubility in water and, therefore, bodily fluids.¹⁹⁸ Arsine, which is highly toxic, is discussed in Chap. 124. Trivalent arsenicals include arsenic trioxide (As₂O₃), tetra-arsenic tetrasulfide (realgar; As₄S₄), and diarsenic trisulfide (orpiment; As₂S₃). Realgar and orpiment were used by the Chinese to treat malignancies, diarrhea, and infections of the chest and liver.¹³⁹ Organic arsenicals vary in toxicity. Arsenobetaine, which is synthesized from inorganic arsenic by fish and crustaceans, and arsenosugars, which are synthesized by fish, crustaceans, and algae, have very low toxicity.^{12,63,131} In contrast, the organoarsenical medication melarsoprol, used to treat the meningoencephalitic stage of African trypanosomiasis, is highly toxic and similar to inorganic

arsenite.^{27,187}

TABLE 89–1. Sources of Exposure to Arsenic

Inorganic

Occupational/manufacturing

Animal feed (additive)

Brass/bronze

Ceramics/glass

Computer chips (same as semiconductors)

Dyes/paints

Electron microscopy

Fireworks (Chinese)

Fossil fuel combustion—coal

Herbicides

Insecticides/pesticides

Metallurgy

Mining

Rodenticides

Semiconductors (gallium arsenide)

Smelting—copper, lead, zinc, sulfide minerals

Soldering

Wood preservatives

Medicines/contaminated xenobiotics

Chemotherapy (acute promyelocytic leukemia)

Depilatory

Herbals/alternative medicines

Homeopathic remedies

Kelp

“Moonshine” ethanol

Opium

Other

Contaminated well water

Contaminated foods/candies, eg, licorice

Organic

Melarsoprol (trypanocidal)

Thiacetarsamide (heartworm therapy in dogs)

Seafood (arsenobetaine)

TABLE 89–2. Regulations and Guidelines Applicable to Arsenic and Arsenic Compounds			
Agency	Guideline Description	Concentration	Source
Air			
ACGIH	TLV (TWA) for arsenic and inorganic arsenic compounds	0.01 mg/m ³	ACGIH 2004
NIOSH	REL (15-min ceiling limit) for arsenic and inorganic compounds	0.002 mg/m ³	NIOSH 2005
	IDLH for arsenic and inorganic compounds	5 mg/m ³	
OSHA	PEL (8-hour TWA) for arsenic organic compounds (general industry, construction, and shipyard)	0.5 mg/m ³	OSHA 2005 29 CFR 1910.1000; 1926.55; 1915.1000
	PEL (8-hour TWA) for general industry for arsenic inorganic compounds	10 µg/m ³	OSHA 2005 29 CFR 1910.1018
Water			
EPA	National primary drinking water standards for arsenic		EPA 2002
	MCL	10 µg/L (10 ppb)	
	MCLG	Zero	
FDA	Bottled drinking water	10 µg/L	FDA 2005 21 CFR 165.110
WHO	Drinking water quality guidelines for arsenic	10 µg/L	WHO 2004
ACGIH			ACGIH 2004
Confirmed human carcinogen			
EPA/NTP			IRIS 2007 / NTP 2005
IARC			IARC 2007

ACGIH = American Conference of Governmental Industrial Hygienists; CFR = Code of Federal Regulations; DWEL = drinking water equivalent level; EPA = Environmental Protection Agency; FDA = Food and Drug Administration; IARC = International Agency for Research on Cancer; IDLH = immediately dangerous to life or health; IRIS = Integrated Risk Information System; MCL = maximum contaminant level; MCLG = maximum contaminant level goal; MW = molecular weight; NIOSH = National Institute for Occupational Safety and Health; NTP = National Toxicology Program; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; TLV = threshold limit value; TWA = time-weighted average; WHO = World Health Organization.

PHARMACOLOGY/PHYSIOLOGY

As₂O₃ has been used successfully to treat APLM. The role of arsenic in our pharmacopeia is expanding; its efficacy in treating various other leukemias, lymphomas, and multiple myeloma, as well as a variety of solid tumors such as breast cancer, colon cancer, lung cancer, hepatocellular carcinoma, colorectal cancer, renal cell carcinoma, and osteosarcoma is being studied.^{38,122,159}

As₂O₃ is administered therapeutically for treating APLM in doses of 0.15 to 0.16 mg/kg/d by either the intravenous or oral route.^{124,126,201,202,205} At this dose its beneficial effects occur predominantly by initiating cellular apoptosis when arsenic concentrations reach 0.5 to 2.0 µmol/L. Apoptosis is triggered by several mechanisms. The trivalent arsenic (As³⁺) ion binds to mitochondrial membrane sulfhydryl (SH) groups, damaging mitochondrial membranes and collapsing membrane potentials. Cytochrome c is released from the damaged mitochondria, with subsequent activation of caspases 9, 3, and 8 and initiation of apoptosis. Cells may be more susceptible if the intracellular concentrations of catalase and glutathione peroxidase (H₂O₂ scavenging enzymes) and glutathione-S-transferase (responsible for conjugating glutathione to xenobiotics) are reduced.^{44,65,79,110,191} As₂O₃ also facilitates apoptosis by down-regulating gene expression of BCL2, a prosurvival protein that protects against apoptosis.³⁶ Finally, As₂O₃ can arrest cells early in mitosis, subsequently leading to apoptosis.⁹²

Low-dose As₂O₃ treatment (0.08 mg/kg/d) beneficially promotes cell differentiation of APL cells when arsenic concentrations reach 0.1 to 2.0 µmol/L. This differentiation is impaired by the promyelocytic leukemia-retinoic acid receptor α (PML-RARα) oncoprotein. This oncoprotein results from the APLM-defining translocation of chromosomes 15 and 17. The PML portion of this oncoprotein plays a key role in leukemogenesis by interfering with RARα activity that is

essential for normal myeloid cellular development. As^{3+} degrades this PML portion, freeing $\text{RAR}\alpha$ to facilitate cell differentiation.^{44,154,161}

Melarsoprol is a trivalent organic arsenical compound used in Africa and parts of Europe to treat the meningoencephalitic stages of both species of African trypanosomes. It is ineffective against American trypanosomiasis and is available in the United States only directly from the Centers for Disease Control and Prevention (CDC), as it is not approved by the US Food and Drug Administration (FDA). The mechanism of action is still poorly understood but may be related to inhibition of glycolysis and oxidation-reduction reactions. The pharmaceutical compound also contains dimercaprol (BAL), which seems to reduce toxicity without diminishing effectiveness. The therapeutic use of melarsoprol can produce many of the toxic effects that occur with inorganic arsenic, including fever, encephalopathy, and acute cerebral edema with seizures and coma. Whether these effects are caused by drug toxicity or by an immune reaction elicited by trypanosomal antigens is unknown.^{27,171,187} Other adverse effects include vomiting, abdominal pain, peripheral neuropathy with hypersensitivity reactions, hypertension, myocardial damage, and albuminuria. Hemolysis can occur in patients with glucose-6-phosphate dehydrogenase deficiency, and erythema nodosum can occur in patients with leprosy.^{27,171} In a study of the usefulness of melarsoprol as a treatment for refractory or advanced leukemia, efficacy was very limited, and reported adverse effects included fatigue, vomiting, diarrhea, vertigo, fever, seizures, headache, back pain, and injection site pain.²⁰⁶

TOXICOLOGY/PATHOPHYSIOLOGY

Investigations of the pathophysiologic effects induced by toxic doses of arsenic are discussed below. The apoptotic mechanisms³⁰ thought to be responsible for some therapeutic effects of As_2O_3 have not been well studied in toxicity models, but limited evidence suggests that cell necrosis may be more important.

Trivalent Arsenic

The primary biochemical effect of As^{3+} is inhibition of the pyruvate dehydrogenase (PDH) complex (Fig. 89–1). Normally, dihydrolipoamide is recycled to lipoamide, a necessary cofactor in the conversion of pyruvate to acetylcoenzyme A (acetyl-CoA). As^{3+} binds the sulfhydryl groups of dihydrolipoamide, blocking lipoamide regeneration.¹⁸⁶ Acetyl-CoA is a central molecule in metabolism, and the resulting decrease leads to several deleterious effects:

- Decreased citric acid cycle activity and thus decreased adenosine triphosphate (ATP) production.
- Disruption of oxidative phosphorylation, which leads to production of hydrogen peroxide and oxygen radicals.
- Decreased gluconeogenesis that can worsen hypoglycemia. Pyruvate carboxylase catalyzes the conversion of pyruvate to oxaloacetate (initial step in gluconeogenesis), and this reaction requires the carboxylation of biotin, a CO_2 carrier attached to pyruvate carboxylase. Biotin cannot be carboxylated unless acetyl-CoA is attached to the enzyme.^{187,211}

FIGURE 89–1. Effect of trivalent arsenicals (As^{3+}) on pyruvate dehydrogenase (PDH) complex. (A) The PDH complex is composed of the three enzymes, which use thiamine pyrophosphate (TPP) and lipoamide as cofactors to decarboxylate pyruvate and form acetyl CoA. (B) Arsenic interferes with the regeneration of lipoamide from dihydrolipoamide, thereby altering the function of the PDH complex.

In the citric acid cycle, oxidation of α -ketoglutarate to succinyl-CoA uses an α -ketoglutarate dehydrogenase complex that contains the same cofactors as the PDH complex, including lipoamide. Succinyl-CoA is necessary for production of porphyrins and amino acids, and deficiency may contribute to the anemia and wasting that occurs with chronic arsenic poisoning. Arsenic inhibition of thiolase, the catalyst for the final step in fatty acid oxidation, also impairs ATP production. Diminished fatty acid oxidation results in decreased acetyl-CoA, in the loss of the reduced form of nicotinamide adenine dinucleotide (NADH) and the reduced form of flavin adenine dinucleotide (FADH₂) (electron carriers reduced during fatty acid breakdown whose subsequent oxidation yields ATP). As³⁺ also inhibits glutathione synthetase, glucose-6-phosphate dehydrogenase (required to produce nicotinamide adenine dinucleotide phosphate {NADPH}), and glutathione reductase.⁸ These inhibitions result in decreased concentrations of reduced glutathione, which is required to facilitate arsenic metabolism, protect red blood cells (RBCs) from oxidative damage, maintain hemoglobin in the ferrous state, and scavenge hydrogen peroxide and other organic peroxides.

Arsenic affects cardiac repolarization currents. When toxicity occurs, the result is ventricular dysrhythmias, including torsade de pointes. An in vitro study of cells exposed to As³⁺ demonstrated blockade of the delayed rectifier channels I_{Ks} and I_{Kr}. Interestingly, activation of I_{K-ATP}, a weak inward rectifier channel, also occurred; this activation could potentially counteract some of the effects of As³⁺ on the I_{Ks} and I_{Kr} channels.⁶⁰

Animal experiments with phenylarsine oxide, a trivalent arsenical, demonstrate inhibition of insulin-induced glucose transport involving vicinal (adjacent) sulfhydryl groups, as well as β cell damage in pancreatic islets attributed to inhibition of the α -ketoglutarate dehydrogenase complex.²⁵ The impaired glucose transport, plus the inhibited gluconeogenesis, can lead to glycogen depletion and hypoglycemia.¹⁸⁸ Several animal experiments indicate improved central nervous system (CNS) glucose content¹⁸⁷ and increased in survival time with glucose treatment.¹⁸⁷

Effects on RBCs include decreased membrane fluidity and ATP depletion.²⁴⁶ Chronic arsenic exposure is associated with vascular disease; in vitro studies demonstrate inhibition of endothelial cell proliferation and glycoprotein synthesis in addition to lipid peroxidation.³⁷ A study on rodent and human platelets demonstrates increased platelet aggregation and arterial thrombosis.¹³³ Noncirrhotic hepatic portal fibrosis can develop. In a controlled study where mice chronically ingested water containing equal parts As³⁺ and As⁵⁺ for up to 15 months, the development of portal fibrosis was preceded by decreased hepatic glutathione (GSH) concentration, increased lipid peroxidation, and diminished concentrations or activities of numerous enzymes involved in regenerating GSH or scavenging free radicals.¹⁹⁶ Proposed mechanisms by which arsenic induces cancer include DNA damage induced by a dimethyl sulfide (DMS)-derived peroxy radical, gene amplification, replacing phosphate in DNA during replication, increased cell proliferation, and decreased DNA repair efficiency.^{17,115,249} Experimental evidence and human studies support a number of etiologic or contributing factors for skin keratosis and cancer,¹ including chronic stimulation of keratinocyte-derived growth factors such as transforming growth factor- α (TGF- α), impaired methylation, mutation in the p53 tumor-suppressor gene, inhibition of poly(adenosine diphosphate {ADP}-ribose) polymerase vital for DNA repair, and interference with mitotic spindle and microtubular function.^{7,81,105,137,248} Pigmentary changes also occur, and hyperpigmentation is attributed to increased melanin.

Pentavalent Arsenic

Several mechanisms contribute to the toxicity of As⁵⁺. As⁵⁺ can be reduced to As³⁺.^{106,231} As⁵⁺ also resembles phosphate chemically and structurally, may share a common transport system for cellular uptake with phosphate,¹⁰⁶ and can inhibit oxidative phosphorylation by substituting for inorganic phosphate (P_i) in the glycolysis reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase (Fig. 89–2).^{34,189} The resulting unstable product, 1-arseno-3-phosphoglycerate, spontaneously hydrolyzes to 3-phosphoglycerate, so glycolysis continues but the ATP normally produced during conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate is lost. Uncoupling may also occur if ADP forms ADP-arsenate, instead of ATP, in the presence of As⁵⁺. The ADP-arsenate rapidly hydrolyzes, thus uncoupling oxidative phosphorylation.

FIGURE 89–2. Pathophysiologic effects of As^{5+} (As^{5+} ; arsenate). (A) Arsenate (chemical formula AsO_4^{3-}) substitutes for inorganic phosphate (P_i ; * indicates substitutions), bypassing the formation of 1,3-bisphosphoglycerate (1,3-BPG), and thus losing the ATP formation that occurs when 1,3-BPG is metabolized to 3-phosphoglycerate. (B) Energy loss also occurs if arsenate substitutes for P_i and blocks the formation of ATP from ADP. ADP = adenosine diphosphate; ATP = adenosine triphosphate.

PHARMACOKINETICS AND TOXICOKINETICS

Absorption

Inorganic arsenic is tasteless and odorless and can be absorbed by the gastrointestinal (GI), respiratory, intravenous, and mucosal routes. GI absorption is facilitated by increased solubility and smaller particle size, and it occurs predominantly in the small intestine, followed by the colon. Poorly soluble trivalent compounds such as As_2O_3 are less well absorbed than more soluble trivalent and pentavalent compounds that, in aqueous solution, have an oral bioavailability greater than 90%. Therefore, when placed in an aqueous solution, As_2O_3 is more toxic than an identical dose of undissolved As_2O_3 eaten in food because of its failure to dissolve, thereby limiting absorption.²²⁸ Organic arsenicals tend to be well absorbed; for example, a rodent study demonstrated approximately 70% GI absorption of the commonly used organic arsenical herbicide, dimethylarsinic acid (cacodylic acid).²⁰⁸ Systemic absorption via the respiratory tract depends on the particulate size, as well as the arsenic compound and its solubility. Large, nonrespirable particles are cleared from the airways by ciliary action and swallowed, allowing GI absorption to occur. Respirable particles lodging in the lungs can be absorbed over days to weeks or remain unabsorbed for years.^{28,243} Dermal penetration of arsenic through intact skin does not pose a risk for acute toxicity but potentially may be problematic with chronic application. Arsenic acid (H_3AsO_4) applied to intact skin in rhesus monkeys resulted in absorption of a mean of 2.0% to 6.4% of the applied dose.²⁴¹ Skin irritation and damage may increase systemic absorption.^{78,190}

Pharmacokinetics of Arsenic Trioxide

Intravenous administration of a single 10-mg dose of As_2O_3 to eight patients showed mean pharmacokinetic values as follows: maximum plasma concentration (Cp_{max}) of $6.85 \mu\text{mol/L}$, α elimination half-life ($t_{1/2 \alpha}$) of 0.89 ± 0.29 hours, and β elimination half-life ($t_{1/2 \beta}$) of 12.13 ± 3.31 hours.²⁰² In six patients, only 1% to 8% of the daily dose was eliminated in a 24-hour urine. Repeat pharmacokinetic studies on day 30 of treatment were not statistically different.²⁰² Another study of patients receiving a single dose of 5 mg of As_2O_3 intravenously demonstrated mean pharmacokinetic values as follows: Cp_{max} of $2.6 \mu\text{mol/L}$, $t_{1/2 \alpha}$ of 1.41 hours, $t_{1/2 \beta}$ of 9.41 hours, serum clearance of 1.98 L/h , and area under the plasma drug concentration versus time curve (AUC) of $12.7 \mu\text{mol/L/h}$. A single dose of 10 mg intravenously showed a Cp_{max} of $6.7 \pm 0.3 \mu\text{mol/L}$.²⁰¹ As_2O_3 10 mg given orally for APL demonstrated total plasma and blood AUC values that were 99% and 87%, respectively, of the corresponding values reported for a 10-mg intravenous dose administered in the same nine patients.¹²⁴

A study in humans receiving intravenous radioarsenic isotope (^{74}As) showed arsenic clearing from the blood in three phases:

- Phase 1 (2 to 3 hours)—Arsenic is rapidly cleared from the plasma with a $t_{1/2}$ of 1 to 2 hours; more than 90% may be cleared during this phase because of redistribution to tissue and renal elimination.
- Phase 2 (3 hours to 7 days)—A more gradual plasma decline occurs, with an estimated $t_{1/2}$ of 30 hours.
- Phase 3 (10 or more days)—Clearance continues from the plasma slowly with an estimated $t_{1/2}$ of 300 hours.¹⁵⁰

The rapid clearance in phase 1 explains why blood testing for arsenic is unreliable, except early in acute poisoning.

Initial distribution is predominantly to liver, kidney, muscle, and skin. The skin is rich in sulfhydryl groups; the elimination $t_{1/2}$ of arsenic by the skin was estimated to be one month in a rabbit study.⁶¹ Distribution to brain also occurs quickly. In the ^{74}As study, 0.30% of the administered dose was found in brain biopsy samples in the first hour postinfusion. This peak declined to 0.16% by day 7.¹⁵⁰ Ultimately, arsenic distributes to all tissues. In the single patient in this study who was followed for 18 days, 96.6% of the total injected arsenic dose was recovered in the urine. Fecal arsenic recovery was less than 1% of the total dose.¹⁵⁰ Other studies in humans demonstrate renal arsenic elimination of 46% to 68.9% within the first 5 days postingestion.^{29,32,111,179} Approximately 30% is eliminated with a half-life of greater than one week, while the remainder is slowly excreted with a half-life of greater than one month.^{29,149} Fecal elimination is considerably less, with reported amounts as much as 6.1% in humans.²¹³ Canine studies have revealed that the mechanisms of urinary elimination of unchanged arsenic and its methylated metabolites are via glomerular filtration and tubular secretion; active reabsorption also occurs.²²¹

Arsenic crosses the placenta and accumulates in the fetus,¹⁴⁰ but three studies of breast milk excretion from women exposed to drinking water with arsenic concentrations of approximately 200 $\mu\text{g/L}$ came to disparate conclusions. Breast milk arsenic concentrations were low in these studies, and only one of them demonstrated a correlation between maternal arsenic concentrations and concentrations in breast milk.^{52,67,195} The authors of one of the two negative studies suggest that breast feeding actually protects the infant from arsenic exposure.⁶⁷

Metabolism, by adding methyl groups, occurs primarily in the liver, as well as in the kidneys, testes, and lungs (Fig. 89–3). If the arsenic is pentavalent, approximately 50% to 70% of As^{5+} will first be reduced to As^{3+} .^{51,209,229} This bioactivation step requires the oxidation of glutathione⁵⁸ and can begin within 15 minutes of exposure.²²⁹ S-adenosylmethionine (SAM) is the primary methyl donor. Nonenzymatic methylation is also demonstrated in an in vitro study using human liver cytosol; here, methylcobalamin (methyl B_{12}) was the methyl donor.²⁵⁵ Dietary and vitamin deficiencies, as well as high doses of inorganic arsenic, may diminish the ability to methylate arsenic, and folate supplementation lowers blood arsenic concentrations in a folate-deficient population.^{15,75–77,93,97,98,176,178,230} However, a study in pregnant Bangladeshi women showed efficient arsenic methylation despite nutritional deficiencies.¹³⁶ Addition of one methyl group produces monomethyl-arsenic acid (MMA^{5+}); adding a second methyl group produces dimethylarsinic acid (DMA^{5+}). Production of a trivalent intermediate in this reaction, monomethylarsonous acid (MMA^{3+}), is catalyzed by MMA^{5+} reductase. In rabbits this is the rate-limiting enzyme in the biotransformation pathway; however, no data exist to confirm a similar role in human metabolism.^{227,256} Conversion of MMA^{5+} to DMA^{5+} is catalyzed by a methyltransferase. Genomic studies have begun to identify gene polymorphisms in these pathways that are associated with variations in arsenic metabolism and toxicity.^{3,175}

FIGURE 89–3. Metabolism of arsenate [As^{5+}] and arsenite [As^{3+}]. DMA, dimethylarsinic acid; GSH = glutathione; MMA = monomethylarsonic acid; SAHC = S-adenosylhomocysteine; SAM = S-adenosylmethionine. The asterisk (*) denotes MMA^{5+} reductase, the rate-limiting enzyme in rabbit studies of arsenic metabolism; the analogy to humans is unknown.

These monomethylation and dimethylation steps were previously thought to detoxify arsenic, but this has been questioned because of the generation of these trivalent intermediates, which are more toxic than the parent compounds.²²⁵ Estimated human LD_{50} (median lethal dose for 50% of test subjects) doses were reported to be As_2O_3 , 1.43 mg/kg; MMA^{5+} , 50 mg/kg; and DMA^{5+} , 500 mg/kg. However, it is important to note that the doses cited for MMA and DMA apply to arsenic existing in the pentavalent form (As^{5+}). Studies in animals and cell cultures indicate that MMA^{3+} may be more toxic than As^{3+} .^{144,173,174} Cytotoxicity studies in human hepatocytes revealed descending toxicity of arsenic and its metabolites as follows: $\text{MMA}^{3+} > \text{arsenite} > \text{arsenate} > \text{MMA}^{5+} = \text{DMA}^{5+}$.¹⁷³ Thus, toxicity increases with the formation of MMA^{3+} .

There is some evidence that these findings have clinical relevance. In a study from a blackfoot disease–hyperendemic area of Taiwan, lower capacity to methylate inorganic arsenic to DMA^{5+} was associated with increased risk of blackfoot disease. The capacity to methylate arsenic to DMA^{5+} was measured as the ratio of DMA^{5+} to MMA^{5+} and the ratio of MMA^{5+} to the sum of As^{3+} and As^{5+} .²¹⁹ In addition, a cohort study found that the odds of premalignant skin lesions increased with increasing urinary MMA^{5+} and decreasing urinary DMA^{5+} .³ They also found that there was an increased risk of skin lesions associated with genetic polymorphisms of glutathione S-transferase and borderline increased risk with polymorphisms of methylenetetrahydrofolate reductase. The authors suggested that the conversion of MMA^{5+} to DMA^{5+} may be saturable and that arsenic metabolism and toxicity are affected by genetics.³ An additional nested case-controlled study of this cohort confirmed that folate deficiency and DNA hypomethylation were risk factors for skin lesions.¹⁷⁷

Arsenobetaine (AsB) is also well absorbed orally and is excreted unchanged in the urine.²²⁸ Elimination occurs more rapidly than with inorganic arsenic. In a study involving human volunteers, 25% was excreted within 2 to 4 hours, 50% by 20 hours, and 70% to 83.7% after 166 hours. A two-compartment exponential model shows nearly 50% of the AsB eliminated, with a first compartment $t_{1/2}$ of 6.9 to 11.0 hours and a second compartment $t_{1/2}$ of 75.7 hours.¹¹¹

CLINICAL MANIFESTATIONS

Inorganic Arsenicals

Toxic manifestations vary, depending on the amount and form, route, and chronicity of arsenic exposure. Other influencing factors include individual variations in methylation and excretion. Larger doses of a potent compound, such as As_2O_3 , will rapidly produce manifestations of acute toxicity, whereas chronic ingestion of substantially lower amounts of As^{5+} in groundwater will result in different clinical findings over time. Manifestations of subacute toxicity can develop in patients who survive acute poisoning, as well as in patients who are slowly poisoned environmentally.

Acute Toxicity. GI signs and symptoms of nausea, vomiting, abdominal pain, and diarrhea, which occur 10 minutes to several hours following ingestion, are the earliest manifestations of acute poisoning by the oral route. The diarrhea has been compared to cholera in that it may resemble “rice water.” Severe multisystem illness can ensue with extensive exposure. Cardiovascular signs, ranging from sinus tachycardia and orthostatic hypotension to shock, can develop. Reported cases have mimicked myocardial infarction or systemic inflammatory response syndrome, with intravascular volume depletion, capillary leak, myocardial dysfunction, and diminished systemic vascular resistance.^{16,22,24,85,112,200} Acute encephalopathy can develop and progress over several days, with delirium, coma, and seizures attributed to cerebral edema and microhemorrhages.^{71,200} Seizures may be secondary to dysrhythmias, and the underlying cardiac rhythm should be assessed. Seizures apparently secondary to torsade de pointes associated with a prolonged QT interval developed 4 days to 5 weeks after acute arsenic ingestion.^{22,83,207} Acute respiratory distress syndrome (ARDS) and respiratory failure, hepatitis, hemolytic anemia, acute kidney injury (AKI), rhabdomyolysis, other ventricular dysrhythmias, and death can occur.^{24,69,88,156,222} Death may occur after suddenly developing bradycardia, followed by asystole.^{24,112,141} Fever may develop, misleading the practitioner to diagnose sepsis.^{62,112} Hepatitis can occur and may be a result of altered intrahepatic heme metabolism causing an increased synthesis of bilirubin or a result of altered protein transport between hepatocytes.⁶ AKI failure may be secondary to ischemia caused by hypotension, tubular deposition of myoglobin or hemoglobin, renal cortical necrosis, and direct renal tubular toxicity.^{26,80,197,222} Glutathione depletion may be contributory.¹⁰³ Unusual complications include phrenic nerve paralysis, unilateral facial nerve palsy, pancreatitis, pericarditis, and pleuritis.^{18,256} Fetal demise has been reported, with toxic arsenic concentrations found in the fetal organs.^{24,140}

Acutely poisoned patients with less severe illness may experience gastroenteritis and mild hypotension that persist despite antiemetic and intravenous crystalloid therapies. Hospitalization and continued intravenous fluids may be required for several days.¹³² The prolonged character of the GI symptoms is atypical for most viral and bacterial enteric illnesses and should alert the physician to consider arsenic poisoning, especially if there is a history of repetitive GI illnesses. A metallic taste or oropharyngeal irritation, mimicking pharyngitis, can occur.^{24,100} GI ulcerative lesions and hemorrhage are reported.^{71,85} Toxic erythroderma and exfoliative dermatitis result from a hypersensitivity reaction to arsenic.²¹⁴

In the days and weeks following an acute exposure, prolonged or additional signs and symptoms in the nervous, GI, hematologic, dermatologic, pulmonary, and cardiovascular systems can occur. Encephalopathic findings of headache, confusion, decreased memory, personality change, irritability, hallucinations, delirium, and seizures may develop and persist.^{62,74,192} Sixth cranial nerve palsy and bilateral sensorineural hearing loss are reported.^{50,83} Peripheral neuropathy typically develops 1 to 3 weeks after acute poisoning, although in one series nine patients developed maximal neuropathy within 24 hours of exposure.^{50,100,132,241} Sensory symptoms develop first, and diminished to absent vibratory sense may be present. Progressive signs and symptoms include numbness, tingling, and formication with physical findings of diminished to absent pain, touch, temperature, and deep-tendon reflexes in a stocking-glove distribution. Superficial touch of the extremities may elicit severe or deep aching pains, a finding that also occurs with thallium poisoning (**Chap. 102**). Motor weakness may then develop. The most severely affected patients manifest an ascending flaccid paralysis that mimics Guillain-Barré syndrome.^{50,100,132} Respiratory findings can include dry cough, crackles, hemoptysis, chest pain, and patchy interstitial infiltrates.^{100,172} These findings may be misinterpreted as viral or bronchitic disease. Leukopenia, and less commonly anemia and thrombocytopenia, occur from days to 3 weeks after an acute exposure, but resolve as bone marrow function returns.^{108,135}

Dermatologic lesions can include patchy alopecia, oral herpetiform lesions, a diffuse pruritic macular rash, and a brawny nonpruritic desquamation (**Chap. 18**). Diaphoresis and edema of the face and extremities can develop.¹ Mees’ lines (transverse striate leuconychia of the nails) are 1- to 2-mm wide horizontal nail bands that represent disturbed nail matrix keratinization (**Fig. 89–4**). They are uncommon in arsenic poisoning. A minimum of 30 days after exposure is required for the lines to extend visibly beyond the nail lunulae.^{100,248} Contact dermatitis has been reported from topical exposure in an occupational setting. Other possible toxic manifestations of subacute inorganic arsenic toxicity include nephropathy, fatigue, anorexia with weight loss, torsade de pointes, and persistence of GI symptoms.^{16,145}

FIGURE 89-4. Mees' lines, parallel white bands across the nails result from exposures to metals, radiation, and chemotherapeutic agents, among others. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Chronic Toxicity. Malignant and nonmalignant skin changes, hypertension, diabetes mellitus (DM), and peripheral and cerebral vascular disease, as well as lung, bladder, and hepatic malignancies are associated with drinking water containing arsenic that is consumed by study populations.^{47,152,170,180,252} The skin is very susceptible to the toxic effects of arsenic; multiple dermatologic lesions have been reported in populations suffering from hydroarsenicism.^{148,252} Alterations in pigmentation occur first, with hyperpigmentation being the most common. Hypopigmentation ("raindrop" pattern) can also occur (Fig. 89-5). Hyperkeratoses typically develop on the palms and soles, but can be diffuse (Fig. 89-6). Squamous and basal cell carcinomas and Bowen's disease (intraepidermal squamous cell carcinoma) may occur. Bowen's disease usually proliferates in multiple sites, especially on the trunk, and is noted for developing on sun-protected areas. Latency periods for developing keratoses, Bowen's disease, and squamous cell carcinoma were 28, 39, and 41 years, respectively, in 17 patients chronically exposed to environmental or medicinal arsenic.^{56,247} GI symptoms of nausea, vomiting, and diarrhea are less likely but can occur. Hepatomegaly was present in 120 of 156 patients with hydroarsenicism; liver biopsy in 45 cases revealed a noncirrhotic portal fibrosis in 91.1%.¹⁴⁸ Rodent studies also demonstrate hepatic fibrosis from inorganic arsenic exposure.¹⁹⁶ Portal hypertension and hypersplenism have occurred.^{148,196} Hepatic angiosarcomas are linked to arsenic exposure.^{48,114,130}

Some, but not all, population studies in areas of Bangladesh, Taiwan, and the United States with arsenic-contaminated water show an increased prevalence of DM, pulmonary fibrosis, and other organ system effects.^{39,117,182,183,220} A cross-sectional drinking water study from the United States revealed an odds ratio of 3.58 for prevalence of type 2 DM among those at the 80th percentile, as compared to those at the 20th percentile, despite a median total arsenic concentration of only 7.1 ppb.^{129,160} However, a cross-sectional study in Bangladesh did not find a relationship between arsenic exposure and DM.³⁹ Animal studies demonstrate that arsenic can decrease insulin-mediated uptake of glucose by cells and can also disrupt insulin transcription factor signal transduction.^{169,236} In a study from West Bengal, restrictive lung disease was reported in 9 of 17 patients, and a restrictive plus obstructive pattern occurred in another 7 cases.¹⁴⁸ Lung disease has also been noted in other populations.⁹⁰ Proposed mechanisms include arsenic-induced inflammation and oxidative stress.¹⁶⁶ Aplastic anemia and agranulocytosis are documented in patients exposed to arsenic.⁶² A dose-response relationship between arsenic exposure and vascular disease is reported in several populations.²³⁸ After adjusting for age, sex, hypertension, DM, cigarette smoking, and alcohol consumption, a significant relationship was observed with cerebrovascular disease in a region of Taiwan.⁴⁷ Blackfoot disease, an obliterative arterial disease of the lower extremities, occurring in Taiwan, is linked to chronic arsenic exposure,^{35,218} as is ischemic heart disease.³³ The incidence of Raynaud's phenomenon and vasospasm was reported to be increased in smelter workers exposed to arsenic, compared with a control group.¹²⁸ Encephalopathy and peripheral neuropathy are the neurologic manifestations most commonly reported.^{21,99} Electromyographic studies of 33 patients with chronic ingestion of arsenic-contaminated water revealed 10 patients with findings consistent with sensory neuropathy. The minimum duration of exposure was 2 years. Interestingly, three of these patients consumed water with an arsenic concentration that only slightly exceeded the contaminant concentration of 50 ppb previously permissible in the United States.¹⁰²

Arsenic is classified as a definite carcinogen by the International Agency for Research on Cancer (IARC, Group 1) and the National Toxicology Program (NTP). Cancers known to develop include lung, skin, and bladder.^{12,49,107,195,204} Transitional cell bladder carcinoma was the most common type in one large epidemiologic study.⁴⁶ However, the exposure threshold of concern remains controversial.¹⁵¹ A critical literature review of animal and human studies found that exposure to environmental arsenic was unlikely to cause reproductive or developmental toxicity.⁵⁹ However, a more recent rodent study revealed fetal growth retardation and neurotoxicity at doses relevant to human exposure and in the absence of maternal toxicity.²³⁷ More concerning, two recent drinking water cohort studies from Bangladesh showed small but statistically significant increases in birth defects and fetal loss.^{125,182,226} In addition to possibly increasing the risk of birth defects, there is also cohort and cross-sectional evidence that in utero or early childhood exposure may be associated with persistent neurocognitive effects in children.^{31,39,54,94,95,117,217,234,239,240} Finally, there is evidence that in utero or early childhood exposure to arsenic in drinking water increases the risk of malignant and nonmalignant lung diseases in young adults.²⁰⁴ In summary, there is accumulating evidence of persistent adverse effects from in utero or early childhood exposure, but additional prospective studies are needed to confirm these findings by decreasing the effects of confounding and bias that may explain the results.

Many of the questions regarding the chronic health effects of exposure to arsenic in drinking water are currently being investigated in the Health Effects of Arsenic Longitudinal Study (HEALS). This study was designed to evaluate the health effects of a full range of drinking water arsenic exposures, including mortality, premalignant and malignant skin tumors,

pregnancy outcomes, and children's cognitive development.⁵

This study is a prospective cohort study in Araihaazar, Bangladesh. Participants were between the ages of 18 and 75 years and married, although both members of a couple were not required to enroll. A total of 11,764 subjects enrolled, 6704 women and 5042 men. The participation rate in the initial enrollment was 97.5% of those approached.⁵ Of those who agreed to participate, 98% completed an extensive questionnaire that included demographic and lifestyle components and a validated food-frequency questionnaire. They also participated in a clinical examination with an extensive skin evaluation. More than 90% of this group also provided blood and spot urine arsenic samples.⁵

Approximately one third of the participants consumed water in each of three groups: greater than 100 µg/L, 25 to 100 µg/L, and less than 25 µg/L. Average urinary concentrations of arsenic were approximately 140 µg/L.

Many studies from this cohort have been published. Studies of persons with arsenic-induced skin lesions have shown increasing risk of disease as exposure increases.^{4,13} Modification of risk was noted in relationship to nutritional status, sunlight exposure, smoking, and some occupational exposures such as fertilizers and pesticides.^{41,42,153} A dose-response relationship was also found for other health effects, including total mortality,¹⁴ cardiovascular disease,⁴⁰ respiratory symptoms,¹⁶⁷ proteinuria,⁴³ oral cavity lesions,²¹⁰ and neurologic effects.^{91,168} Biannual follow-up of this cohort continues.

Adverse Drug Effects: Arsenic Trioxide

The most common adverse effects are dermatologic (skin dryness, pigmentary changes, maculopapular eruptions with or without pruritus); GI (nausea, vomiting, anorexia, diarrhea, and dyspepsia); hematologic (leukemoid reactions); hepatic (elevation of aminotransferase concentrations typically less than or equal to 10 times the upper limit of normal values, with a reported incidence of 20% with low-dose and 31.9% with conventional-dose therapy²⁰¹); cardiac (prolonged QT interval in 40%–63% of patients, first-degree atrioventricular block, ventricular ectopy, monomorphic nonsustained ventricular tachycardia, torsade de pointes, asystole, and death);^{194,201,205,224,245} facial edema; and neurologic (paresthesias, peripheral neuropathy, and headache). All of these effects occurred more commonly in one case series with conventional-dose therapy (0.16 mg/kg/d) when compared to low-dose therapy. The majority of patients are treated symptomatically without discontinuing As₂O₃ treatment. Leukemoid reactions, defined as white blood cell counts greater than $50 \times 10^9/L$, develop in nearly 50% of patients between 14 and 42 days of beginning treatment. Such patients are at risk for intracerebral hemorrhage or infarction and for the APML syndrome. This syndrome is similar to the differentiation syndrome (DS), which was formerly known as the retinoic acid syndrome.¹⁵⁵ The remission induction treatment phase is the period of greatest risk.²⁰² Common clinical findings in this syndrome include pulmonary interstitial infiltrates and/or pleural effusions, dyspnea, tachypnea, fluid retention, myalgias, arthralgias, fever, and weight gain; approximately 20% to 25% of patients treated with arsenic trioxide will develop one or more signs or symptoms of this syndrome.^{146,159,194,201,202}

Although a theoretical concern, there is currently no evidence of increased risk of secondary malignancies in treated patients. Continued close follow-up will be necessary to evaluate whether secondary malignancy risk will increase over time.⁶⁵

DIAGNOSTIC TESTING

Timing of testing for arsenic must be correlated with the clinical course of the patient and whether the poisoning is acute, subacute, chronic, or remote with residual clinical effects. To properly interpret laboratory measurements, confounding factors, such as food-derived organic arsenicals or accumulated arsenic (DMA and arsenobetaine) in patients with chronic kidney disease, must be considered.^{55,260,261} Failure to understand potential confounders, as well as the time course of arsenic metabolism, clearance, and effect on laboratory parameters, can cause erroneous assessment of possible arsenic poisoning.

Urine and Blood

Diagnosis ultimately depends on finding an elevated urinary arsenic concentration. In an emergency, a spot urine may be sent prior to beginning chelation therapy. A markedly elevated arsenic concentration verifies the diagnosis in a patient with characteristic history and clinical findings, but a low concentration does not exclude arsenic toxicity.²³⁵ In nine acutely symptomatic patients, initial spot urine arsenic concentrations ranged from 192 to 198,450 µg/L.¹¹⁶ Definitive diagnosis of arsenic exposure hinges on finding a 24-hour urinary concentration equal to or greater than 50 µg/L, 100 µg/g creatinine, or 100 µg total arsenic. A study on arsenic exposure from drinking water showed excellent correlations between spot and 24-hour urine arsenic concentrations. There are not enough data to determine if this relationship holds true in acutely poisoned patients, so a 24-hour collection is still preferred.³² Challenge testing with dimercaptopropane sulfonate (DMPS) has been performed in individuals exposed to arsenic in drinking water and clearly increases arsenic excretion; however, it also alters the percentages of the arsenic species recovered compared with controls and has not been correlated with clinical

effects.¹¹ All urine should be collected in metal-free polyethylene containers; acid-rinsed containers are not recommended since the acid alters the arsenic species.⁶⁸ If testing is performed by an outside reference laboratory, specimens from acutely ill patients should be sent via express transportation with a request for a rapid result.

When interpreting slightly elevated urinary arsenic concentrations, laboratory findings must also be correlated with the history and clinical findings, because seafood ingestion is reported to transiently elevate urinary total arsenic excretion up to 1700 µg/L.¹² When seafood arsenic is a consideration, speciation of arsenic can be accomplished by high-performance liquid chromatography (HPLC) separation, followed by inductively coupled plasma-mass spectrometry (ICPMS), HPLC via ion-pair chromatography coupled with hydride-generation atomic-fluorescence spectrometry (HGAFS), or by hydride generation coupled with cold-trap gas chromatography-atomic absorption spectrometry. These techniques separate AsB, As³⁺, As⁵⁺, MMA, and DMA.⁶⁸ Arsenobetaine can also be directly measured by silica-based cation-exchange separation, followed by atomic absorption spectrometry.¹⁶² Two other methods, selective hydride-generation atomic-absorption spectrometry (HGAAS) and resin-based ion-exchange chromatography, do not directly measure AsB; instead, they indirectly derive this value by subtracting the sum of all measured arsenic species from the total arsenic concentration.¹⁶² If arsenic speciation cannot be done, the patient can be retested after a one-week abstinence from fish, shellfish, and algae food products.

Conditions under which urine is stored can affect total arsenic recovery, as well as proportionality of the species. The various arsenic species—arsenate (As⁵⁺), arsenite (As³⁺), MMA, DMA, and AsB—remain stable for 2 months in urine stored without preservatives at either -4°F (-20°C; freezer) or 39.2°F (4°C; refrigerator); AsB is stable for 8 months under these conditions. Storage for longer than 2 months can alter the recovery of various species. Addition of 0.1% hydrochloric acid (HCl) facilitates reduction of arsenate to arsenite and also decreases MMA and DMA concentrations. Acid-washed collection containers should not be used if measurement of the various arsenic species is planned. Total arsenic recovery can be diminished by any of the following: specimen storage for greater than 2 months, acidification, or testing using HPLC-ICPMS and HPLC-HGAFS, since all these methods usually require that the samples be filtered prior to undergoing HPLC separation.⁶⁸

Diagnostic evaluation of chronic toxicity should include laboratory parameters that may become abnormal within days to weeks following an acute exposure. Tests should include a complete blood count, renal and liver function tests, urinalysis, and 24-hour urinary arsenic determinations. Complete blood count findings can include a normocytic, normochromic, or megaloblastic anemia; an initial leukocytosis followed by development of leukopenia, with neutrophils depressed more than lymphocytes, and a relative eosinophilia; thrombocytopenia; and a rapidly declining hemoglobin, indicative of hemolysis or a GI hemorrhage.¹²⁷ Basophilic stippling of RBCs can be seen; this can occur in other toxic and clinical disorders. Karyorrhexis, a rupture of the RBC cell nucleus with chromatin disintegration into granules that are extruded from the cell, and dyserythropoiesis are reported in both lead- and arsenic-toxic patients. Both findings are caused by arsenic-induced inhibition of DNA synthesis and damage to the nuclear envelope.⁶⁴ The karyorrhexis can occur within 4 days and resolve by 2 weeks after poisoning, and may be an early indication of arsenic toxicity.¹²⁷ Elevated serum creatinine, aminotransferases, and bilirubin, as well as depressed haptoglobin concentrations, may develop. Urinalysis may reveal proteinuria, hematuria, and pyuria. Cerebrospinal fluid examination in patients with CNS findings can be normal or exhibit mild protein concentration elevation, measured at 26.5 mg/dL in one case.¹⁰⁰ Urinary arsenic excretion in subacute and chronic cases varies inversely with the postexposure time period, but low-concentration excretion can continue for months after exposure. In a study of 41 cases of arsenic-induced peripheral neuropathy, most patients with a neuropathy of 4 to 8 weeks duration had total 24-hour urinary arsenic measurements of 100 to 400 µg.¹⁰⁰

Hair and Nail Testing

In cases of suspected arsenic toxicity, in which the urinary arsenic measurements fall to less than toxic concentrations, analysis of hair and nails may yield the diagnosis. Arsenic can be detected in the proximal portions of hair within 30 hours of ingestion.²⁵³ Inorganic arsenic is the form best absorbed by these tissues and the form most commonly found in human poisoning cases; small amounts of methylated metabolites may also be detected.¹⁸¹ Arsenobetaine has not been found in hair and tissues in human and animal studies.^{250,251} Hair grows at rates varying from 0.7 to 3.6 cm per month, with a mean rate of 1 cm per month.²⁴² The Society of Hair Testing has made the following recommendations for collection of hair specimens, although they are only validated for testing drugs of abuse: (a) collect approximately 200 mg of hair from the posterior vertex region of the scalp using scissors to cut as close to the scalp as possible, and (b) tie the hairs together, wrap in aluminum foil to protect from environmental contamination, and store at room temperature.²⁴² Nails grow approximately 0.1 mm per day. Total replacement of a fingernail requires 3 to 4 months, whereas toenails require 6 to 9 months of growth. These facts, plus the frequency of hair cutting, should be considered when estimating the usefulness of measuring arsenic levels in these tissues. The normal values of the testing laboratory should be used to determine whether arsenic concentrations are elevated. In cases of remote toxicity, hair and nail arsenic measurements may or may not be elevated, depending on the time elapsed since exposure. Sequential hair analysis to assess the time(s) of exposure can be

performed by solid sampling graphite furnace atomic absorption spectrophotometry or by x-ray fluorescence spectrometry.^{118,215,216}

Other Tests

Abdominal radiographs might demonstrate radiopaque material in the GI tract soon after an ingestion.^{2,45,85,86,101} However, even after an acute ingestion, the absence of radiopaque materials on abdominal radiographs is reported.⁵³ The incidence of positive radiographs after an ingestion is unknown, and a negative radiograph should not eliminate arsenic as a diagnostic consideration. Electrocardiographic changes reported include QRS widening, QT prolongation, ST-segment depression, T-wave flattening, ventricular premature contractions, nonsustained monomorphic ventricular tachycardia, and torsade de pointes.^{20,164,205,224} Nerve conduction studies (NCS) can confirm or diagnose clinical or subclinical axonopathy. Both the sensory nerve action potential (SNAP) and the motor compound muscle action potential (CMAP) measure the number of axons that are available to conduct impulses. Since the sensory studies are more sensitive than motor studies in detecting axonal degeneration and demyelination, decreased SNAP measurements better indicate subclinical neuropathy. In motor nerve studies, the amplitude (height of the CMAP) is a more sensitive measure of the number of axons that can conduct impulses than is the conduction velocity; this can be explained by the pattern of axonal destruction as opposed to myelin injury (which mainly affects conduction velocity). Nerve biopsies have confirmed disintegration of both axons and myelin in patients with arsenic-induced peripheral neuropathy; the axonal loss begins distally in the lower extremities and is initially scattered. Thus, conduction along the remaining functional axons can be sufficient to produce normal or only slightly decreased conduction measurements on NCS.^{82,100,119,132,158,163}

MANAGEMENT

General

Acute arsenical toxicity is life threatening and mandates aggressive treatment. Advanced life support monitoring and therapies should be initiated when necessary, but with a few caveats. Careful attention to fluid balance is important because cerebral and pulmonary edema may be present. Xenobiotics that prolong the QT interval, such as the class IA, class IC, and class III antidysrhythmics, should be avoided whenever possible ([Chaps. 16 and 64](#)). Potassium, magnesium, and calcium concentrations should be maintained within normal range to avoid exacerbating a prolonged QT interval. Glucose concentrations and glycogen stores should be maintained parenterally with dextrose and hyperalimentation solutions or with enteral feedings, in view of their beneficial effects in experimental models of arsenic poisoning.^{138,187,188,211}

GI decontamination of patients acutely poisoned with arsenic is controversial. Arsenic poorly adsorbs to activated charcoal, cholestyramine, and bentonite.¹⁸⁵ Moreover, significantly poisoned patients usually have nausea and vomiting and may have altered mental status, which make activated charcoal administration difficult. Despite these concerns, activated charcoal in conjunction with airway protection if necessary is recommended because of the relatively low likelihood of harming the patient and the hope that preventing even a small amount of absorption might prevent or lessen the potentially disastrous consequences of arsenic poisoning. If radiopaque material is visualized in the GI tract, whole bowel irrigation can be administered until the radiopaque material is no longer visualized on repeat abdominal radiograph. Continuing nasogastric suction may be important in removing arsenic resecreted in the gastric or biliary tract. Arsenite was still detectable in the gastric aspirate in three patients 5 to 7 days following an ingestion.¹⁴³ There is no clinical experience with the use of N-acetylcysteine to increase glutathione concentrations, although an animal model suggested a protective effect.¹⁸⁴

In cases of chronic toxicity, patients should be removed from the arsenic source, and gastric decontamination should be performed if there is evidence of arsenic in the GI tract. Arsenic can be readily removed from skin with soap, water, and vigorous scrubbing. In this situation, when homicidal intent is suspected, all hospital visitors should be closely monitored, and outside nutritional products should be forbidden.

Chelation Therapy

Chelators. Dimercaprol (BAL) and 2,3-dimercaptosuccinic acid (succimer) are the two chelators available in the United States. A third drug, DMPS, is distributed by Heyl, a German pharmaceutical company, as Dimaval, but it is not approved or marketed in the United States ([Antidotes in Depth: A25 and A26](#)). All contain vicinal dithiol moieties that bind arsenic to form stable 1,2,5-arsadithiolanes ([Fig. 89–7](#)), and all are most effective when administered in doses equimolar to the arsenic burden.¹⁵⁷ Dosing regimens and adverse effects are listed in [Table 89–3](#).

FIGURE 89–7. 1,2,5-Arsadithiolane adducts with BAL, DMPS, and DMSA.

TABLE 89–3. Chelators for Arsenical Poisoning

<i>Dosage</i>	<i>Adverse Effects</i>
BAL 3–5 mg/kg IM every 4–6 hours	Hypertension, febrile reaction, diaphoresis, nausea, vomiting, salivation, lacrimation, rhinorrhea, headache, painful injection, injection site sterile abscess, hemolysis in G6PD-deficient patients, chelation of essential metals (prolonged course)
SUCCIMER 10 mg/kg/dose orally every 8 hours for 5 days, then 10 mg/kg/dose every 12 hours	Nausea, vomiting, diarrhea, abdominal gas and pain, transient elevations of hepatic aminotransferases and alkaline phosphatase concentrations, rash, pruritus, sore throat, rhinorrhea, drowsiness, paresthesias, thrombocytosis, eosinophilia
DMPS (not FDA approved) Dose: 5 mg/kg/dose IM, administered as a 5% solution Day 1: q6–8h Day 2: q8–12h Day 3 and thereafter: q12–24h End point: for chelation is a 24 hour urinary arsenic concentration of <50 µg/L	Allergic reactions, increased copper and zinc excretion, nausea, pruritus, vertigo, weakness, toxic epidermal necrolysis

G6PD = glucose-6-phosphate dehydrogenase; IM = intramuscularly.

The decision to initiate chelation therapy should depend on the clinical condition of the patient as well as the laboratory results for arsenic in urine, hair, or nails. A severely ill patient with known or suspected acute arsenic poisoning should be chelated immediately, prior to laboratory confirmation. In the United States, BAL remains the initial chelating drug for acute arsenical toxicity.¹⁵⁷ In a series of 33 patients who had coma, seizures, or both, 24 patients were treated with BAL within 6 hours (mean, 1 hour) and 75% survived, compared with a survival rate of 45% of nine patients who were treated later (range, 9–72 hours; mean, 30 hours).⁶² Cases of subacute and chronic toxicity can await rapid laboratory confirmation prior to beginning chelation, unless the clinical condition deteriorates.

In a cellular study of glucose uptake impaired by a lipophilic arsenical, BAL was superior to succimer and DMPS in restoring cellular equilibrium.¹⁵⁷ A human case series found increased survival with early use of BAL and improvement in encephalopathy within 24 hours of initiating therapy.⁶² However, other acute cases treated promptly with BAL developed peripheral neuropathy.¹³² In a study of subacute cases with peripheral neuropathy, BAL accelerated neurologic recovery but did not affect the overall recovery rate.⁵⁰ Despite starting BAL therapy 8 hours postexposure, a man who had ingested 2.15 g of arsenic developed severe toxicity and neurologic deficits.⁷⁰ Most concerning are the animal experiments indicating that BAL shifts arsenic into the brain and testes, two organs that have blood–organ barriers susceptible to this lipophilic drug.^{10,104,121} It is clear that BAL has limitations, and that a safer, more effective intracellular/extracellular parenteral chelator is needed.

Succimer is an oral hydrophilic analog of BAL and is the chelator of choice for subacute and chronic toxicity. It has proven effective in animal studies and in reported human cases.^{10,120,134,142,203} In mice exposed to sodium arsenite, succimer

was more effective than either DMPS or BAL in decreasing lethality and more potent than BAL in restoring activity in the pyruvate dehydrogenase complex.¹⁰ It is equal or superior to BAL in speeding arsenic elimination.¹⁵⁷ Liver function tests and essential metal concentrations should be monitored in patients requiring prolonged therapy.^{73,87}

DMPS is also a water-soluble analog of BAL. It is not approved for use in the United States. It can be administered by the oral, intravenous, and intramuscular routes. It is eliminated from the body more slowly than succimer and has the advantage of intracellular as well as extracellular distribution.⁷ It predominantly binds MMA^{3+} and possibly removes the MMA^{3+} from endogenous ligands. The DMPS– MMA^{3+} complex is eliminated in the urine.^{9,11,84} It may also work by synergistically increasing the nonenzymatic methylation of As^{3+} .²⁵⁵ Two brothers ingested nearly pure arsenic trioxide (1 and 4 g each) and were treated with intravenous and oral DMPS. The brother who ingested 4 g developed hypotension, AKI, respiratory insufficiency, and asystolic cardiac arrest. DMPS was started 32 hours postingestion, and the patient survived with normal renal function and no neurologic dysfunction. His sibling had a milder course; DMPS was started 48 hours postingestion, and there were no neurologic sequelae on follow-up examination.¹⁵⁶ DMPS significantly increased biliary excretion of arsenic in a guinea pig model but did not increase fecal excretion. The latter is most likely a result of enterohepatic recirculation of the DMPS–As complex.¹⁸⁵ However, in another guinea pig model, the addition of oral cholestyramine to either DMPS or DMSA but not to BAL increased fecal arsenic excretion.¹⁵⁷

D-Penicillamine has not demonstrated efficacy in chelating or reversing the biochemical lesions of arsenic and should not be used. Its previous advantage of oral administration is no longer relevant with the availability of succimer.

Because of the limitations of currently available chelators, research is ongoing to find better chelators to treat arsenic toxicity. For example, some analogs of succimer, especially its monoisoamyl ester, have increased intracellular penetration relative to the parent compound and increase survival in arsenic-poisoned rats.^{72,113} In addition to improved chelators, other treatments for arsenic toxicity are being investigated. Some rodent studies have suggested that certain micronutrients, such as zinc or selenium, can decrease arsenic toxicity.⁷² However, early findings from the HEALS cohort are mixed. A cross-sectional substudy from this group revealed an inverse relationship between the severity of skin lesions and dietary intake of folate; pyridoxine; riboflavin; and vitamins A, C, and E.²⁵⁴ In contrast, another study from the same cohort did not find a statistically significant relationship between the severity of skin lesions and supplementation with vitamin E, selenium, or both.²³³ Until more data are available, nutritional supplementation, in the absence of dietary deficiency, remains controversial.

Hemodialysis. Hemodialysis removes negligible amounts of arsenic, with or without concomitant BAL therapy, and is not indicated in patients with normal kidney function.^{23,96,147} In patients with AKI, hemodialysis clearance rates have ranged from 76 to 87.5 mL/min, with or without concomitant BAL therapy.²³² In two acutely toxic patients with AKI, total arsenic removed during a 4 hour dialysis measured 4.68 mg in one and 3.36 mg in the other. Concomitant 24 hour urinary arsenic excretions were 3.12 mg and 2.03 mg, respectively. When renal function returned, however, the 24 hour urinary excretion of arsenic far exceeded that recovered with dialysis, with reported amounts of 18.99 mg in the first patient and 75 mg in the second patient.²³² There are no published rigorous data regarding hemodialysis removal of a water-soluble complex such as DMPS–As.¹²³

SUMMARY

- Environmental contamination of water sources has become a major health problem in many countries, including the United States.
- Arsenicals produce multisystem toxicity by a variety of pathophysiologic mechanisms.
- A thorough understanding of inorganic arsenic metabolism and excretion as well as the different clinical manifestations of acute, subacute, and chronic toxicity are necessary to avoid misdiagnosis.
- Chelation therapy with BAL in the United States, or with DMPS elsewhere, if available, should be started immediately in the severely ill patient.
- Treatment can await laboratory results for patients with subacute or chronic toxicity, unless clinical deterioration intervenes.

A25 ANTIDOTES IN DEPTH

Dimercaprol (British Anti-Lewisite or BAL)

Mary Ann Howland

INTRODUCTION

British anti-Lewisite (BAL) (2,3-dimercaptopropanol; dimercaprol) is a metal chelator used clinically in conjunction with edetate calcium disodium (CaNa₂EDTA) for lead encephalopathy and severe lead toxicity.^{23,30} In this, BAL should precede the first dose of CaNa₂EDTA by 4 hours to prevent redistribution of lead to the central nervous system (CNS). BAL has a narrow therapeutic index, BAL must be administered intramuscularly (IM) because it is formulated in peanut oil. Oral succimer is used for patients with less severe lead toxicity. The roles for BAL in arsenic and mercury poisoning have diminished since the development of succimer and the investigational chelator 2,3-dimercaptopropane sulfonate (DMPS). BAL is still indicated when the gastrointestinal tract is compromised.

HISTORY

Investigation into the use of sulfur donors as antidotes was precipitated by the World War II threat of chemical warfare with lewisite (dichloro[2-chlorovinyl]arsine) and mustard gas (dichlorodiethyl sulfide [ClCH₂CH₂]₂S).^{1,31,32} Both are vesicants that cause tissue damage when combined with protein sulfhydryl groups (Chap. 132).³⁵ The investigations of Stocken and Thompson at Oxford led to the discovery of the dithiol 2,3-dimercaptopropanol (or BAL) that combines with lewisite to form a stable five-membered ring.^{40,42}

PHARMACOLOGY

Chemistry

BAL has a molecular weight of 124.2 Da and a specific gravity of 1.21.³³ It is an oily liquid with only 6% weight/volume water solubility, 5% weight/volume peanut oil solubility, and a disagreeable odor. Aqueous solutions are easily oxidized and therefore unstable. Peanut oil stabilizes BAL and benzyl benzoate (in the ratio of one part BAL to two parts of benzyl benzoate) renders the BAL miscible in peanut oil.³⁶

Mechanism of Action

The sulfhydryl groups of dimercaprol form chelates with certain metals, which are then excreted in the urine. Lead, arsenic, and inorganic mercury salts are the metals most amenable to chelation with BAL.

Pharmacokinetics

There are no recent studies of the pharmacokinetics of BAL. The limited information available was first described in the late 1940s.^{1,24} Serum concentrations of BAL peak about 30 minutes after IM administration, and distribution occurs rapidly.^{36,39} Within 2 hours after IM administration to rabbits, serum concentrations rapidly fall. Urinary excretion of BAL

metabolites, perhaps partially as glucuronic acid conjugates, accounted for nearly 45% of the dose within 6 hours and 81% of the dose within 24 hours.^{36,38} Very little is excreted unchanged in the urine.³⁶ BAL is concentrated in the kidney, liver, and small intestine.³⁴ BAL can also be found in the feces, suggesting that enterohepatic circulation exists. Hemodialysis may be useful in removing the BAL–metal chelate in cases of kidney failure.^{23,29,41}

ROLE OF DIMERCAPROL IN ARSENIC EXPOSURE

Animal Studies

The fear of lewisite attack causing skin lesions led researchers to investigate the potential for cutaneous application of BAL.⁴⁰ This was based on the limited water solubility and high lipid solubility of BAL. In a rodent model, low concentrations of topical BAL were very effective both in preventing lewisite-induced toxicity and in reversing toxicity when administered within one hour of skin exposure.^{33,35} In rabbits, ophthalmic application of BAL proved effective in preventing corneal destruction if applied within 20 minutes of exposure.²³ Additionally, urinary arsenic concentrations were significantly increased after the application of BAL.³⁵

The effectiveness of both parenteral single-dose and multiple-dose BAL against lewisite and other arsenicals was studied in rabbits. When begun within 2 hours of lewisite exposure, BAL injections of 4 mg/kg every 4 hours led to a 50% survival of exposed rabbits. This dosing regimen was demonstrated to be one-seventh of the maximum tolerated dose of BAL.¹⁷

The most recent animal studies demonstrate that although BAL increases the LD₅₀ (median lethal dose for 50% of test subjects) of sodium arsenite, the therapeutic index of BAL is low and arsenic redistribution to the brain occurs.^{4,6,7,20,37} In these same animal models, succimer and DMPS also increased the LD₅₀ but with a better therapeutic index and without causing redistribution to the brain.^{3,4}

Ophthalmic damage caused by lewisite is partly a result of the liberation of hydrochloric acid, which results in an acid injury causing localized superficial opacity of the cornea and deep penetration of lewisite into the cornea and aqueous humor with resultant rapid necrosis. In an experimental model, a 5% BAL ointment or solution applied within 2 minutes of exposure prevented the development of a significant reaction; application at 30 minutes limited the reaction, but did not prevent permanent damage.²¹

Human Studies

Experiments in human volunteers who were given minute amounts of arsenic demonstrated that BAL increased urinary arsenic concentration by approximately 40%, with maximum excretion occurring 2 to 4 hours after BAL administration.⁴⁴ BAL was subsequently used in the treatment of arsenical dermatitis resulting from organic arsenicals used to treat syphilis. When applied to affected skin, topical BAL produced erythema, pruritus, and dysesthesias, but it had no adverse effects on unaffected skin. IM BAL produced both subjective and objective improvement, limited the duration of the arsenical dermatitis, and increased urinary arsenic elimination.^{13,27,28}

In a study of 227 patients with inorganic arsenic poisoning, maximal efficacy and minimal toxicity were achieved when 3 mg/kg of BAL was administered IM every 4 hours for 48 hours and then twice daily for 7 to 10 days. This regimen resulted in complete recovery in six of seven patients with severe arsenic-induced encephalopathy and demonstrated the importance of administering BAL as soon as possible after the exposure. Of 33 patients with severe arsenic-induced encephalopathy, 18 of 24 (75%) treated within 6 hours survived, versus only four of nine (44%) treated after a delay of at least 72 hours.¹⁶ Furthermore, the effectiveness of BAL was also demonstrated in three patients who were treated successfully after mistakenly receiving 10 to 20 times the therapeutic dose of oxophenarsine hydrochloride (Mapharsen). A fourth patient, treated with inadequate doses of BAL, died.¹⁶ These cases support the effectiveness of BAL in treating arsenic-induced agranulocytosis, encephalopathy, dermatitis, and probably arsenical fever.¹⁵

When BAL first became more widely available, 42 children were treated following arsenic ingestions, and their results were compared with a historical group of 111 untreated children who had also ingested arsenic.⁴⁵ The percentage of children exhibiting symptoms on presentation were similar between groups (46%), but in the group of children treated with BAL there were fewer deaths (zero versus three), a shorter average hospital stay (1.6 versus 4.2 days), and fewer cases of persistent symptoms at 12 hours (0% versus 29.3%).

ROLE OF DIMERCAPROL IN MERCURY EXPOSURE

Because mercury also reacts with sulfhydryl groups, animal studies were performed to assess the affinity and ability of thiols to competitively chelate inorganic mercury and prevent toxicity. As in the case of arsenic, the dithiol BAL was more

effective than the monothiol 1-thiosorbitol in preventing mercury-induced death and uremia.¹⁹ The clinical efficacy of BAL in treating inorganic mercury poisoning was substantiated in patients who ingested mercuric chloride.^{25,26} Thirty-eight patients ingesting more than 1 g of mercuric chloride who were treated with BAL within 4 hours of exposure were compared with historical controls.²⁵ There were no deaths in the 38 patients treated with BAL as compared to 27 deaths in the 86 untreated patients. Death typically resulted from hemorrhagic gastritis and kidney failure.²⁵ BAL is particularly useful for patients who have ingested a mercuric salt, as the associated gastrointestinal toxicity of the mercuric salt limits the potential of an orally administered antidote such as succimer.⁴³

Animal models demonstrate that when BAL is administered following poisoning from elemental mercury vapor or exposure to short-chain organic mercury compounds, brain concentrations of mercury may increase.^{9,12} As a result BAL therapy is not recommended in these circumstances.^{2,5,23} (Chap. 98).

ROLE OF DIMERCAPROL IN LEAD EXPOSURE

BAL may be used in combination with CaNa_2EDTA to treat patients with severe lead poisoning. In all other cases, succimer has become the chelator of choice. When treating patients with lead encephalopathy, it is essential to administer the BAL first, followed 4 hours later by CaNa_2EDTA with a second dose of BAL. This regimen prevents the CaNa_2EDTA from redistributing lead into the brain.^{14,15} Providing two different chelators also reduces the blood lead concentration significantly faster than either one alone, and maintains a better molar ratio of chelator to lead.¹⁴ Once the mobilization of lead has begun, it is important to provide uninterrupted therapy to prevent redistribution of lead to the brain (Chap. 96).¹⁴

ADVERSE EFFECTS AND SAFETY ISSUES

BAL has an LD_{50} in mice via intraperitoneal administration of 90 to 180 mg/kg, which is significantly lower than that of CaNa_2EDTA at 4000 to 6000 mg/kg, succimer at 2480 mg/kg, and DMPS at 1100 to 1400 mg/kg.²

Less than 1% of 700 IM injections resulted in minor reactions, such as pain at the injection site, among patients who received 2.5 mg/kg of BAL every 4 to 6 hours for 4 doses.¹³ When doses of 4 mg/kg and 5 mg/kg were given, the incidence of adverse effects rose to 14% and 65%, respectively.¹⁶ At these higher doses, the following symptoms were reported in decreasing order of frequency: nausea, vomiting, headache, burning sensation of lips, mouth, throat, and eyes, lacrimation, rhinorrhea, salivation, muscle aches, burning and tingling of extremities, tooth pain, diaphoresis, chest pain, anxiety, and agitation.²⁷ These effects were maximal within 10 to 30 minutes of exposure and usually subsided within 30 to 50 minutes.¹⁶ Elevations in systolic and diastolic blood pressure and tachycardia commonly occurred and correlated with increasing doses.^{23,30} Thirty percent of children given BAL may develop a fever that can persist throughout the therapeutic period.²³ In addition, in children, a transient reduction in the percentage of polymorphonuclear leukocytes may also occur.²³ Doses above 5 mg/kg should not be administered because of the high risk of adverse reactions. Doses above 25 mg/kg can be expected to produce a hypertensive encephalopathy with convulsions and coma.⁴⁵

BAL is not very effective in the presence of arsenic-induced hepatotoxicity.²⁸ Moreover, in rats, preexistent hepatotoxicity was exacerbated when BAL was used for treatment of arsenic poisoning. Therefore, unless the hepatotoxicity is considered to be arsenic induced, hepatic dysfunction is a contraindication to BAL use.³⁵ BAL should not be used for patients poisoned by methylmercury because animal studies demonstrate a redistribution of mercury to the brain.^{5,23}

Because dissociation of the BAL-metal chelate will occur in acidic urine, the urine of patients receiving BAL should be alkalinized with hypertonic sodium bicarbonate to a pH of 7.5 to 8.0 to prevent kidney liberation of the metal.²³ BAL should be used with caution in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, as it may cause hemolysis²²; a risk-to-benefit analysis must be made because G6PD-deficiency syndromes are variably expressed. In addition, chelators are relatively nonspecific and may bind metals other than those desired, thus causing deficiency of an essential metal. For example, BAL given to mice increased copper elimination to three times normal.¹¹ BAL is formulated in peanut oil; therefore, the patient should be questioned regarding any known peanut allergy and a risk-benefit analysis undertaken. Limited evidence suggests that iron supplements should not be given to patients who are receiving BAL because the BAL-iron complex appears to cause severe vomiting and decreases metal chelation.^{14,15,18}

Unintentional intravenous (IV) infusion of BAL could theoretically produce fat embolism (peanut oil), lipid pneumonia, chylothorax, and associated hypoxia.³⁸

Pregnancy and Lactation

Dimercaprol is pregnancy category C.⁸ There have not been any animal studies evaluating the effects of BAL on reproduction. It is not known whether BAL is harmful to a fetus or is capable of affecting reproduction capability.⁸ There are no data in human poisoning in pregnancy, and BAL should only be administered to a pregnant woman if clearly indicated.⁸

No data address whether BAL or its chelates are excreted in human breast milk.

DOSING AND ADMINISTRATION

No clinical trial has been performed to identify the appropriate dose of BAL. The dosing for BAL is expressed in both mg/m² and mg/kg. BAL should be administered only by deep IM injection. The dose of BAL for lead encephalopathy is 75 mg/m² IM every 4 hours for 5 days in children.^{14,15} As noted earlier, the first dose of BAL should precede the first dose of CaNa₂EDTA by 4 hours. Thereafter, IV CaNa₂EDTA, in a dose of 1500 mg/m²/d (up to a maximum of 2–3 g) as a continuous infusion, or divided into two to four doses, should be administered. These daily doses are equimolar. For adults, the dose of BAL is 4 mg/kg every 4 hours.⁸

The dose of BAL for severe inorganic arsenic poisoning has not been established. One regimen suggests the use of 3 mg/kg IM every 4 hours for 48 hours and then twice daily for 7 to 10 days.¹⁶ Another regimen uses 3 to 5 mg/kg IM every 4 to 6 hours on the first day and then tapers the dose and frequency, depending on the patient’s symptomatology. A third regimen reduces the number of injections by day 2 and terminates therapy within 5 to 7 days⁴⁵ (Table A25–1).

TABLE A25–1. Calculations for Average Deep Intramuscular (IM) BAL Use When Using Body Surface Area (m²)

Child	Average Height (in)	Average Weight (lbs)	m ²	75 mg/m ² Every 4 hours IM ^a	50 mg/m ² Every 4 hours IM ^b
2 year-old boy	36	30.5	0.593	44.5 mg	30 mg
2 year-old girl	35	29	0.57	43 mg	28.5 mg
4 year-old boy	42	39.75	0.73	55 mg	36.5 mg
4 year-old girl	41.75	38.75	0.72	54 mg	36 mg

^aapproximately 4 mg/kg ^bapproximately 3 mg/kg

The dose of BAL for patients exposed to inorganic mercury salts is 5 mg/kg IM initially, followed by 2.5 mg/kg every 12 to 24 hours until the patient appears clinically improved, up to a total of 10 days.⁸

As noted above, the urine should be kept alkaline to avoid dissociation of the BAL–metal chelate.^{10,23}

FORMULATION AND ACQUISITION

Commercially available BAL is a yellow, viscous liquid with a sulfur odor. It is available in 3 mL ampules containing 100 mg/mL of BAL, 200 mg/mL of benzyl benzoate, and 700 mg/mL of peanut oil.⁸ BAL is for deep IM use only.

SUMMARY

- BAL is a metal chelator used clinically in conjunction with CaNa₂EDTA for lead encephalopathy and severe lead toxicity.^{23,30}
- In this instance, BAL should precede the first dose of CaNa₂EDTA by 4 hours.
- The roles of BAL in arsenic and mercury poisonings are being supplanted by oral succimer and the investigational chelator DMPS, which is indicated unless the gastrointestinal tract is compromised.

90 BISMUTH

Rama B. Rao

Bismuth (Bi)		
Atomic number	=	83
Atomic weight	=	208.98 Da
Normal concentrations		
Blood	<	5 µg/dL (239.5 nmol/L)
Serum	<	1 µg/dL (<47.9 nmol/L)
Urine	<	20 µg/L (<95.7 nmol/L)

HISTORY AND EPIDEMIOLOGY

Elemental bismuth is nontoxic. Bismuth salts have therapeutic uses and are responsible for the toxicities described in this chapter. Thus, the term “bismuth” in this chapter refers to bismuth salts. Nearly 300 years ago, bismuth was recognized as medically valuable. It was included in topical salves and oral preparations for various GI disorders. Nephrotoxicity was described as early as 1802. In the early 20th century, acute kidney injury was reported in children administered intramuscular bismuth salts for the treatment of gingivostomatitis.^{7,25,47,48} Administration of bismuth thioglycollate and its related water soluble compounds, triglycollamate and trithioglycollamate, were responsible for the kidney failure, which occurred with as little as one or two treatments.^{8,12,29,34,38,39,55} Children with kidney failure would typically present with abdominal pain, oliguria, anuria, malaise, depressed mental status, and vomiting. Alterations in consciousness usually abated with treatment or resolution of the uremia. After the use of intramuscular injections was abandoned, this form of bismuth-induced kidney failure became uncommon. Syphilis was previously treated with intramuscular bismuth. A rash known as “erythema of the 9th day,” consisting of a diffuse macular rash of the trunk and extremities, occasionally occurred and resolved without intervention.¹⁶

In patients administered “Analbis” antipyretic rectal suppositories, hepatic failure was described histopathologically as yellow atrophy with vacuolization.^{3,22} An investigation of the suppositories suggested that diallylacetic acid, a xenobiotic that is no longer marketed in the United States, and not bismuth, was the hepatotoxin.

Today, bismuth is one of many xenobiotics commonly used in prescription and nonprescription oral preparations for treatment of traveler’s diarrhea, nausea, and vomiting. In addition bismuth-impregnated surgical packing paste is used for the treatment of the flatus and odor associated with ileostomies and colostomies,^{9,57} and as an adjunct in the treatment of ulcers.¹⁴ In the gastrointestinal (GI) tract, bismuth binds to sulfhydryl groups and decreases fecal odor through formation of bismuth sulfide.⁵⁰ Sulfhydryl binding is also the proposed mechanism for the antimicrobial effect of bismuth, causing lysis of *Helicobacter pylori*, the causative bacteria in peptic ulcer formation. Bismuth may also inhibit bacterial enzyme function, as well as prevent adhesion of *H. pylori* to the gastric mucosa.⁵⁶

Epidemics of bismuth-induced encephalopathy, particularly among patients with ileostomies or colostomies, were reported from France, Britain, and Australia. As a result, some countries banned or restricted bismuth preparations to prescription only. Bismuth subsalicylate, which is currently available in the United States as a nonprescription remedy, is still periodically responsible for cases of encephalopathy.^{15,17,30} Other reported causes of bismuth-induced encephalopathy include systemic absorption from bismuth-impregnated surgical packing paste and transdermal absorption from chronic application of a bismuth-containing skin cream.²⁴

In 2006, the Food and Drug Administration (FDA) of the United States issued a warning on an alternative health product known as “bismacine” or “chromacine.” This nonpharmaceutical product is not FDA approved, but was used by some practitioners as an injectable treatment for Lyme disease, for which efficacy data are lacking. The product contains bismuth citrate and was associated with at least one death and other adverse events.²

CHEMISTRY AND TOXICOLOGY

Bismuth is present in nature in both the trivalent and pentavalent forms. The trivalent form of bismuth is used for all medicinal uses, usually as the bismuthyl (BiO) moiety generated by hydrolysis of trivalent bismuth compounds to yield a low solubility alkaline salt. Bismuth salts are divided into four groups based on their water or lipid solubility. Most orally administered bismuth remains in the GI tract, and is subsequently excreted in the feces, with only 0.2% is systemically absorbed.¹⁹ Absorption of some bismuth preparations such as colloidal bismuth subcitrate may increase as gastric pH increases.³⁶ The time to peak absorption ranges between 15 and 60 minutes with high intra- and interindividual variation.^{23,25} The serum-to-blood ratio of bismuth is 1.55.⁴ The distribution and elimination of orally administered bismuth follows a complex, multicompartmental model. The volume of distribution in humans is unknown.^{5,44}

Once in the circulation, bismuth binds to α_2 -macroglobulin, IgM, β -lipoprotein, and haptoglobin. Bismuth rapidly enters liver, kidney, lungs, and bone.⁵¹ Bismuth can cross the placenta and enter the amniotic fluid and fetal circulation.⁵³ It also readily crosses the blood–brain barrier.³⁵ Evidence in a rat model suggests that, when administered intramuscularly, bismuth can enter the central nervous system (CNS) via retrograde axonal transport.⁴⁹ In both animal models and human reports bismuth is identified in the fenestrated membranes of synaptosomes,^{38,41} localizing in the thalamus and cerebellum with diffuse cortical uptake as well.^{25,35} Ninety percent of absorbed bismuth is eliminated through the kidneys, where it induces the production of its own metal-binding protein.⁵¹

Some authors propose three different half-lives to describe the pharmacokinetics of orally administered therapeutic doses of bismuth.^{5,44} The first, a distribution half-life, is approximately 1 to 4 hours. The second, the apparent plasma half-life, lasts 5 to 11 days. The third is the apparent half-life of urinary excretion lasting between 21 and 72 days⁴ with urinary bismuth detected as late as 5 months after the last oral dose.²³

PATHOPHYSIOLOGY

Like other metals, bismuth toxicity involves multiple organ systems. The effect of different bismuth salts can be categorized into four groups based on solubility and GI absorption (Table 90–1).⁴³ The highly lipid soluble compounds such as bismuth subsalicylate or bismuth subgallate are most commonly associated with neurotoxicity.

TABLE 90–1. The Physicochemical Characteristics of Bismuth Salts

Group	Chemistry	Toxicity	Examples
I	Insoluble in water Inorganic	Minimal	Bismuth subnitrate Bismuth subcarbonate
II	Lipid soluble Organic	Neurologic	Bismuth subsalicylate Bismuth subgallate
III	Water soluble Organic	Renal	Bismuth triglycollamate
IV	Hydrolyzable Water soluble Organic	Minimal	Bismuth bicitropeptide

The mechanism of bismuth-induced encephalopathy is thought to be related to neuronal sulfhydryl binding. In patients who die of bismuth encephalopathy, the gray-matter concentration of bismuth is nearly twice that of white matter.²⁵ In a bismuth encephalopathic patient dying from concomitant sepsis, the autopsy revealed loss of cerebellar purkinje cells, which is not expected from sepsis alone.²⁶ The factors predisposing some individuals to encephalopathy from group II bismuth salts, however, are not well defined. Age, gender, and duration of therapeutic use do not predict the likelihood of developing encephalopathy, but typically patients are on chronic bismuth therapy with a lipid soluble (group II) xenobiotic.

CLINICAL MANIFESTATIONS

Acute

Acutely, massive overdoses of bismuth may result in abdominal pain and oliguria or anuria. Acute kidney failure can occur and is not limited to exposure to the water soluble bismuth salts (group III).^{34,39} In reported cases, overdoses of colloidal bismuth subsalicylate or tripotassium dicitratobismuthate (TDC) caused acute tubular necrosis.^{1,18,20,48,52}

Histopathologically, bismuth causes degeneration of the proximal tubule, similar to other metals. While these substances are potentially neurotoxic, signs of encephalopathy are generally absent.^{11,17} In one case, a patient with bismuth-induced kidney failure was described as having diminished deep-tendon reflexes, muscle weakness, and myoclonus, without an alteration in consciousness.¹⁸

Chronic

The most common toxicologic finding associated with repeated therapeutic doses of oral bismuth compounds is a diffuse, progressive encephalopathy.^{11,17} Affected patients exhibit neurobehavioral changes, such as apathy and irritability. With continued exposure, these patients may develop difficulty concentrating, diminished short-term memory, and occasionally, visual hallucinations.^{27,28} A movement disorder characterized by muscle twitching, myoclonus, ataxia, and tremors may ensue.¹¹ This is often described as a myoclonic encephalopathy. Weakness and, rarely, seizures may advance to immobility.^{30,32} With continued bismuth administration these patients can develop coma and die.

Rarely, patients recovering from severe encephalopathy may complain of scapular, humeral, or vertebral pain because of fractures caused by severe neuromuscular manifestations such as myoclonus.¹³

Like several other metals, bismuth can cause a generalized pigmentation of skin. Deposition of bismuth sulfide into the mucosa causes a blue-black discoloration of gums.⁵⁸ This can occur in the absence of toxic effects. Formation of the same compound in the GI tract causes blackening of the stool. Liver failure is rarely reported, except in patients with multisystem organ failure from fatal neurotoxicity.

DIAGNOSIS

The clinician must have an index of suspicion based on the acute or chronic nature of the exposure and the class of bismuth salt ingested. Patients with acute massive overdoses should be evaluated for acute kidney injury, the earliest findings suggestive of which are hematuria and proteinuria on urinalysis. Formation of nuclear inclusion bodies can be identified on renal biopsy or on postmortem examination of the kidney.^{12,40}

The diagnosis of bismuth-induced encephalopathy is based on a history of exposure coupled with diffuse neuropsychiatric and motor findings.²⁸ Other causes of encephalopathy should be entertained and excluded (Table 90–2). An abdominal radiograph will likely demonstrate radiopacities of bismuth in the intestines. Stool likely will be black and test negative for occult blood.

TABLE 90–2. Differential Diagnosis of Bismuth Encephalopathy

- Creutzfeld-Jacob disease
- Ethanol withdrawal
- Lithium toxicity
- Neurodegenerative leukoencephalopathies
- Nonketotic hyperosmolar coma
- Postanoxic and posthypoglycemic encephalopathies
- Progressive multifocal ataxia
- Viral encephalopathies

The presence of bismuth in the blood is confirmatory of exposure, but absolute concentrations correlate poorly with morbidity.⁵ In a review of 310 patients with bismuth-induced encephalopathy, 288 patients (93%) had a blood concentration greater than 10 µg/dL, with the majority of these blood concentrations between 10 and 100 µg/dL.²⁷ Twenty-two patients suffered encephalopathy at blood concentrations below 10 µg/dL.²⁷ In another report, two patients with encephalopathy had blood concentrations of 90 and 250 µg/dL, both of whom recovered when the concentration fell below 50 µg/dL.⁶ Just as blood concentrations do not reflect severity of illness, tissue concentrations also correlate poorly with severity of illness. An example was noted in a patient who recovered from severe encephalopathy. On discharge, he had a low blood bismuth concentration and died 3 months later of unrelated trauma. At autopsy he was found to have an elevated CNS bismuth burden but no reported symptoms at the time of the trauma.¹⁰

The electroencephalographic (EEG) findings of patients with bismuth encephalopathy generally demonstrate nonspecific slow wave changes.^{15,18} In one study, the EEG findings were described in association with blood concentrations. At less than 5 µg/dL, the EEG was normal or demonstrated diffuse slowing. In patients with blood concentrations of less than 150 µg/dL, the findings of sharp wave abnormalities were noted. At higher concentrations (greater than 200 µg/dL), some patients with neurological events, such as myoclonic jerks, did not have corresponding EEG changes. The authors proposed that an elevated body burden might have an inhibitory effect on the cerebral cortex.¹⁰

In encephalopathic patients with blood concentrations greater than 200 µg/dL, diagnostic imaging such as computed tomography may demonstrate a diffuse cortical hyperdensity of the gray matter. These findings tend to resolve with recovery. Magnetic resonance imaging was normal in another encephalopathic patient.¹⁵

TREATMENT

Typically, supportive care results in a complete recovery. Some authors suggest GI decontamination with activated charcoal and polyethylene glycol solution.⁴⁵ Although evidence for this approach is lacking, it appears to be a reasonable initial intervention, especially in patients with severe encephalopathy. In patients with kidney failure, resolution is generally observed with supportive care. The use of chelators in patients with acute overdose without neurotoxicity is probably not indicated.

It is uncertain whether different chelators affect the clinical course of encephalopathic patients. Withdrawal of the source of bismuth results in complete reversal of effects within days to weeks, even in severely ill patients. The precise timing, dosage, indications, and choice of chelator is not known; however, chelation with succimer has few side effects and may potentially limit the potentially fatal complications associated with prolonged immobilization. British anti-Lewisite (BAL), which has more side effects, can be considered in encephalopathic patients with kidney failure in whom no neurological improvement is noted within 48 hours of whole-bowel irrigation and bismuth withdrawal (see Chelation below).

Prevention is the most effective means of avoiding neurotoxicity. Blood concentrations of bismuth are not routinely performed, but a bismuth concentration above 100 ng/mL or symptoms at lower concentrations warrant withdrawal of bismuth therapy.

CHELATION

In general, the data regarding chelation are limited and in vitro and animal models are not clearly predictive of human response. Chelation therapy with BAL is beneficial in experimental models,^{45,48} reportedly beneficial in humans,³¹ and often recommended, although clear evidence of efficacy is lacking. BAL undergoes biliary elimination, offering a major advantage over other chelators in patients who may develop acute kidney injury. One study advocated the addition of dimercaptopropane sulfonate (DMPS), as BAL did not affect hemodialysis clearance, but the addition of DMPS to patients needing hemodialysis was effective in enhancing elimination.⁴⁸ It is uncertain whether the clinical course of the patients was improved. In human volunteers given colloidal bismuth subcitrate, succimer and DMPS, both at a dose of 30 mg/kg, increased urinary elimination of bismuth by 50 fold.⁴⁶

In an animal model, D-penicillamine was most efficacious in enhancing elimination of bismuth. In a human volunteer model using therapeutic doses of tripotassium-dicitrato-bismuthate, however, a single dose of D-penicillamine did not enhance urinary excretion.³³ Based on the above information we would recommend withdrawal of bismuth therapy and whole bowel irrigation as a first intervention. While data on chelation efficacy is lacking, BAL may be used in patients with life threatening encephalopathy unresponsive to initial measures after 48 hours.

BISMUTH DRUG INTERACTIONS AND REACTIONS

The coadministration of proton pump inhibitors (PPIs) may increase the absorption of some bismuth preparations. In a prospective evaluation of patients receiving different treatment regimens for *H. pylori*-induced dyspepsia or peptic ulcer disease, individuals taking PPIs had a statistically significant elevation in their blood bismuth concentrations with three patients exceeding 5000 µg/dL, compared with a similar group administered bismuth without PPIs. The authors suggest that the bismuth preparation used, colloidal bismuth subcitrate, is more soluble and absorbable at the higher gastric pH of patients on PPIs.¹⁹ All these patients received short courses of therapy (2 weeks). While the investigators did not attempt to follow neurobehavioral or neuropsychiatric changes, none of the patients had clinically evident bismuth toxicity.³⁶

Based on this investigation, coadministration of PPIs with longer courses of colloidal bismuth subcitrate should be avoided or only offered with extreme caution. Ranitidine, which is frequently prescribed with a bismuth compound for dyspepsia or ulcer disease, does not affect the pharmacokinetics of bismuth absorption.²³

In the United States, where bismuth subsalicylate is the most common oral bismuth-containing compound, up to 90% of the salicylate is absorbed.^{37,42} Salicylate toxicity has been reported, and salicylate concentrations should be determined in both acute and chronic exposures.^{42,47} Methemoglobinemia from subnitrate salt of bismuth is uncommonly described.²¹

SUMMARY

- Bismuth toxicity may manifest as nephrotoxicity from group III water soluble bismuth salts.
- Encephalopathy, myoclonic jerks, and coma may occur with chronic toxicity of Type II lipophilic bismuth salts.
- Supportive care, WBI, and withdrawal of the bismuth containing compound are the mainstays of treatment.
- The role of chelators is under investigation.
- Salicylate concentrations may be elevated in some cases of chronic bismuth subsalicylate poisoning.

91 CADMIUM

Stephen J. Traub and Robert S. Hoffman

Cadmium (Cd)	
Atomic number	= 48
Atomic weight	= 112.40 Da
Normal concentrations	< 5 µg/L (44.5 nmol/L)
Whole blood	< 3 µg/g creatinine
Urine (24 hour)	< 26.7 nmol/g creatinine

HISTORY AND EPIDEMIOLOGY

Cadmium, atomic number 48, is a transition metal in group IIB of the periodic table. In its pure atomic form, it is a bluish solid at room temperature. It is readily oxidized to a divalent ion, Cd^{2+} . Naturally occurring cadmium commonly exists as cadmium sulfide (CdS), a trace contaminant of zinc-containing ores.³⁶

Cadmium sulfide, cadmium oxide, and other cadmium-containing compounds are refined to produce elemental cadmium, which is used for industrial purposes. When combined with other metals, cadmium forms alloys of relatively low melting points, which accounts for its extensive use in solders and brazing rods. Today, cadmium is primarily used as a reagent in electroplating and in the production of nickel-cadmium batteries. Other uses of cadmium include as a pigment and as a neutron absorber in nuclear reactors. Cadmium salts have also been used as veterinary antihelminthics.¹²

As cadmium processing has increased, so has the incidence of cadmium toxicity. Cadmium toxicity usually occurs after environmental, occupational, or hobby work exposure.

Environmental Exposure

Environmental exposure to cadmium generally occurs through the consumption of foods grown in cadmium contaminated areas. Because cadmium is fairly common as an impurity in ores, areas where mining or refining of ores takes place are the most likely to contain cadmium contamination.

In the 1950s, a mine near the Jinzu River basin in Japan discharged large amounts of cadmium into the environment, contaminating the rice that was a staple of the local food supply. An epidemic of painful osteomalacia followed, affecting hundreds of people, with postmenopausal multiparous women being most affected.⁶⁷ The afflicted were prone to develop pathologic fractures, and were reported to call out “itai-itai” (“ouch-ouch”) as they walked, because of the severity of their pain.²⁸ These symptoms were ultimately linked to the cadmium. Less consequential environmental cadmium exposures have also occurred in Sweden,⁴⁶ Belgium,¹⁰ and China.⁴⁸ Additionally, smokers have higher blood cadmium concentrations than nonsmokers,⁹¹ probably as a result of contamination of soil where the tobacco is grown. This is noteworthy, in that cadmium and tobacco may be synergistic causes of chronic pulmonary disease.⁶³

Occupational and Hobby Exposure

Welders, solderers, and jewelry workers who use cadmium-containing alloys are at risk for developing acute cadmium toxicity due to inhalation of cadmium oxide fumes. Other workers who do not work with metals per se may develop significant chronic cadmium toxicity through exposure to cadmium-containing dust.

Hobbyists who work with cadmium solders have exposures similar to occupational metalworkers. Significant cadmium toxicity in this population is usually the result of metalworking in a closed space with inadequate ventilation and or improper respiratory precautions.

TOXICOKINETICS

There is no known biologic role for cadmium or its salts. Orally ingested cadmium salts are poorly bioavailable (5%–

20%); however, inhaled cadmium fumes (cadmium oxide) are readily bioavailable (up to 90%).⁹⁹ As the only data on cadmium toxicokinetics are derived from work with cadmium salts and oxides, the term “cadmium” in the following discussion refers to these species unless otherwise noted.

After exposure, cadmium is absorbed into the bloodstream, where it is bound to α_2 -macroglobulin and albumin.¹⁰⁰ It is then quickly and preferentially redistributed to the liver and kidney, and to a lesser extent to other organs such as the pancreas, spleen, heart, lung, and testes.²⁵ Cadmium may enter target organs via three mechanisms: zinc and calcium transporters, uptake of cadmium–glutathione or cadmium–cysteine complexes by transport proteins, or endocytosis of cadmium–protein complexes.¹⁰⁶

After incorporation into the liver and kidney, cadmium is complexed with metallothionein, an endogenous thiol-rich protein that is produced in both organs. Metallothionein binds and sequesters cadmium. Slowly, hepatic stores of the cadmium–metallothionein complex (Cd-MT) are released. Circulating Cd-MT is then filtered by the glomerulus. A significant amount is reabsorbed and concentrated in proximal tubular cells,^{19,86,87} explaining why the kidney is a principal target organ in cadmium toxicity.

There is no evidence that cadmium ions are oxidized, reduced, methylated, or otherwise biotransformed in vivo. The volume of distribution (Vd) of cadmium is unknown, but is presumably quite large as a consequence of significant hepatic sequestration. Cadmium distribution and elimination are complex, and an eight-compartment kinetic model has been proposed.⁵⁴ The slow release of cadmium from metallothionein-complexed hepatic stores accounts for its very long biologic half-life of 10 or more years.

PATHOPHYSIOLOGY

Cellular Pathophysiology

Cadmium toxicity results from interaction of the free cation with target cells.^{25,35,61,66,87} Complexation with metallothionein is cytoprotective,^{22,61} and metallothionein functions as a natural chelator with a strong affinity for cadmium.^{18,55} Although metallothionein may play a role in proximal tubular concentration of cadmium, kidney damage is attenuated by metallothionein, as metallothionein-deficient mice are more susceptible to cadmium toxicity than controls.⁶¹

There are several mechanisms by which cadmium interferes with cellular function. Cadmium binds to sulfhydryl groups, denaturing proteins and or inactivating enzymes. The mitochondria are severely affected by this process,¹ which may result in an increased susceptibility to oxidative stress.⁴⁷ Cadmium also interferes with mediators of cell adhesion such as E-cadherin, N-cadherin, and β -catenin.^{72–74} Finally, the demonstrated interference of cadmium with calcium transport mechanisms^{96,97} might lead to intracellular hypercalcemia and, ultimately, apoptosis (Table 91–1).

TABLE 91–1. Chronic and Acute Organ System Effects of Cadmium

Organ	Acute	Chronic
Kidney		Proteinuria Nephrolithiasis
Bone		Osteomalacia
Lung	Pneumonitis	Cancer
Gastrointestinal system	Caustic injury	

Specific Organ System Injury

Kidney. The kidney damage caused by cadmium develops over years. Proteinuria is the most common clinical finding and correlates with proximal tubular dysfunction, which manifests as urinary loss of low-molecular-weight proteins such as β_2 -microglobulin and retinol-binding protein. Cadmium also produces hypercalciuria,⁸³ possibly also via damage to the proximal tubule.

Bone. Cadmium-induced osteomalacia is a result of abnormalities in calcium and phosphate homeostasis, which, in turn, result from renal proximal tubular dysfunction. In one autopsy study, the severity of osteomalacia in cadmium exposed subjects correlated with a decline in the serum calcium-phosphate product.⁹⁰

Lung. Acute cadmium pneumonitis is characterized by infiltrates on chest radiograph and hypoxia. Human autopsy studies^{32,71,84,101} generally show degeneration and or loss of bronchial and bronchiolar epithelial cells.

Gastrointestinal Tract. Based on case reports,^{11,102} ingested cadmium salts are caustic with the potential to induce

significant nausea, vomiting, and abdominal pain, and result in GI hemorrhage, necrosis, and perforation. With respect to their effect on the GI mucosa, cadmium salts act similar to mercuric salts (Chap. 98).

CLINICAL MANIFESTATIONS

Acute Poisoning

Pulmonary/Cadmium Fumes. Cadmium pneumonitis results from inhalation of cadmium oxide fumes. The acute phase of cadmium pneumonitis may mimic metal fume fever (Chap. 124), but in fact, the two entities are distinctly different, with regard to both mechanism and clinical consequences. Whereas metal fume fever is benign and self-limited, acute cadmium pneumonitis can progress to hypoxia, respiratory insufficiency, and death.

Published case reports of patients who develop acute cadmium pneumonitis^{4,5,32,71,84,93,101,105} are strikingly similar in their presentation. Within 6 to 12 hours of soldering or brazing with cadmium alloys in a closed space, patients typically develop constitutional symptoms, such as fever and chills, as well as a cough and respiratory distress.

On initial presentation these patients may have a normal physical examination, oxygenation, and chest radiograph. This relatively benign presentation may lead both to the misdiagnosis of metal fume fever and the underestimation of the severity of illness. As the pneumonitis progresses to acute respiratory distress syndrome (ARDS) (Chap. 124), crackles and rhonchi develop, oxygenation becomes impaired, and the chest radiograph develops a pattern consistent with alveolar filling. Despite aggressive supportive care, death may occur, usually within 3 to 5 days.^{32,71,84,101}

Patients who survive an episode of acute cadmium pneumonitis may develop chronic pulmonary disorders, including restrictive lung disease,^{4,5} diffusion abnormalities,⁴ and pulmonary fibrosis,⁹³ although recovery without sequelae is also reported.¹⁰⁵

Oral/Cadmium Salts. Most acute cadmium exposures are inhalational, and acute ingestions are rare. Based on case report data, GI injury is likely to be the most significant clinical finding after acute ingestion, although other presentations are possible.

In one case,¹¹ a 17 year-old student ingested approximately 150 g of cadmium chloride that she obtained from her school science stockroom. She presented to the emergency department with hypotension and edema of the face, pharynx, and neck. Her condition quickly deteriorated, and she suffered a respiratory arrest. She was intubated and underwent orogastric lavage, chelation with an unspecified agent, and charcoal hemoperfusion. Multisystem organ failure ensued, and she died within 30 hours of presentation. At autopsy, the most significant finding was hemorrhagic necrosis of the upper GI tract. Her blood cadmium concentration was more than 2000 times normal.

In a second reported case a 23 year-old man ingested approximately 5 g of cadmium iodide in a suicide attempt and presented with acute hemorrhagic gastroenteritis.¹⁰² His condition deteriorated, and despite treatment with calcium disodium ethylenediaminetetraacetic acid (CaNa₂EDTA) and supportive measures, he died on hospital day 7. Autopsy did not reveal a specific cause of death.

A 51 year-old man taking multiple nutritional supplements who had no history to suggest cadmium exposure presented with a one month history of fatigue, with laboratory findings suggestive of autoimmune hemolytic anemia. He was treated aggressively for that condition, but developed progressive multisystem organ failure and expired one week after presentation. His blood cadmium concentrations were extraordinarily high, suggesting an acute ingestion, although the source of the cadmium was never determined.⁷⁶

Chronic Poisoning

Nephrotoxicity. The most common finding in chronic cadmium poisoning is proteinuria. Low-molecular-weight proteinuria is usually more significant than, and generally precedes, glomerular dysfunction, although some cadmium exposed workers manifest predominantly glomerular proteinuria.⁷ There is a dose–response relationship between total body cadmium burden and kidney dysfunction,^{10,44,46,67,95} although this relationship may not be as strong at low doses.³⁹ Patients with diabetes mellitus may be particularly susceptible to the nephrotoxic effects of cadmium.³⁷ In most cases, proteinuria is generally considered to be irreversible even after removal from exposure,^{38,52,79} but improvement is sometimes reported.^{60,94} Less clear is the question of whether kidney dysfunction progresses after removal from exposure, with studies showing both stable³⁸ and deteriorating^{42,78,79} function in cadmium exposed workers who are removed from exposure. The routes and duration of exposure, as well as blood and urine cadmium concentrations, differ markedly among these studies, limiting wider applicability of any analysis.

Occupational cadmium exposure is also associated with nephrolithiasis,^{45,82} likely as a result of hypercalciuria.⁸³

Pulmonary Toxicity. Large studies of workers chronically exposed to relatively low concentrations of cadmium fail to demonstrate consistent effects on the lung. In one study of 57 workers with sufficient exposure to cadmium oxide to produce kidney dysfunction, there was no evidence of pulmonary dysfunction, even in those with the greatest cumulative cadmium

exposure.²⁷ In contrast, other studies have reported both restrictive¹⁷ and obstructive^{21,81} changes on pulmonary function tests. Interestingly, a follow-up study of the group with restrictive lung disease showed improvements after cadmium exposure was reduced.¹⁶ The discrepancies in these results may be partly a result of markedly different doses and durations of exposure among the various groups.

Cadmium is associated with pulmonary neoplasia; the carcinogenicity of cadmium is discussed separately (see Cancer below).

Musculoskeletal Toxicity. Cadmium-induced osteomalacia usually occurs in the setting of environmental exposure, as was true in Japan and Sweden.⁴³ Although mentioned in case reports,^{8,52} osteomalacia is generally not a prominent feature of occupational exposure to cadmium. Gender and age differences may explain part of this apparent difference: victims of the original Itai-Itai epidemic were mostly older women, whereas occupational cadmium exposures typically occur in younger men. In addition, differences in cumulative dosing and in route of exposure (oral vs. pulmonary) may partly account for the unique prominence of osteomalacia in patients with environmental exposures. Cadmium exposure is associated with osteopenia and osteoporosis even in areas (such as the United States) where widespread environmental exposure is unlikely.¹⁰³

Hepatotoxicity. Although the liver stores as much cadmium as any other organ, hepatotoxicity is not a prominent feature in humans with cadmium exposure, probably because hepatic cadmium is usually complexed to metallothionein.⁴⁰ The liver is a potential target organ, however, as hepatotoxicity is easily inducible in animals.^{1,25,26,77}

Neurologic Toxicity. Cadmium exposure is linked to olfactory disturbances,^{64,80,89} impaired higher cortical function,⁹⁸ and parkinsonism.^{68,98}

Other Organ Systems. Cadmium induces hypertension in rats,⁵⁹ but human studies have only yielded unconvincing and conflicting results.^{31,58,69,92} Although there is evidence that cadmium may cause immunosuppression affecting both humoral and cell-mediated immunity in animals,²⁴ a single human study showed no overt immunopathology in an occupationally exposed cohort.⁵¹ The testes are clearly a target organ in animal exposures,⁵⁷ but they are not considered a major target organ in humans.

Cancer. Cadmium induces tumors in multiple animal organs, an effect that is exacerbated by zinc deficiency.⁹⁹ In humans, cadmium exposure is associated with lung cancer.⁷⁰ The strength of this association has been questioned because most studies have methodologic problems, such as coexposure to arsenic, a known pulmonary carcinogen.^{9,53} Despite these confounding coexposures, cadmium is officially designated as a human carcinogen by the International Agency for Research on Cancer.⁴¹

DIAGNOSTIC TESTING

Other than to confirm exposure, cadmium concentrations have limited usefulness in the management of the acutely exposed patient. Diagnosis and treatment are based on the history, physical examination, and symptoms. In a patient exposed to cadmium oxide fumes, ancillary tests, such as pulse oximetry and chest radiography, are more useful than actual cadmium concentrations.

In the patient chronically exposed to cadmium, both cadmium concentrations and ancillary testing may prove helpful. Urinary cadmium concentrations, which reflect the slow, steady-state turnover and release of metallothionein-bound cadmium from the liver, are a better reflection of the total body cadmium burden than are whole blood concentrations. In a 22-year follow up study, mortality was higher in those with elevated urine cadmium concentrations, although it was impossible to determine if the cadmium was causative or served as a marker for another process.⁷⁵

Workers at high risk for cadmium toxicity should routinely have urinary protein testing, supplemented with urine and or blood cadmium testing when urinary protein testing is abnormal. Workers with a urinary cadmium concentration greater than 7 µg/g urinary creatinine or a whole blood cadmium concentration greater than 10 µg/L require immediate reassignment to a cadmium-free area. Workers with significant proteinuria (β₂-microglobulin concentrations of 750 µg/g urinary creatinine) should also be reassigned if additional testing confirms cadmium exposure (as defined by a urinary cadmium concentration greater than 3 µg/g urinary creatinine or a whole blood cadmium concentration greater than 5 µg/L). These numbers are reasonable in light of the fact that kidney dysfunction can occur at cadmium concentrations as low as 5 µg/g urinary creatinine,^{20,44} a concentration significantly higher than that of the general US population, 95% of whom have concentrations that are less than 2 µg/g urinary creatinine.¹⁵

MANAGEMENT

Acute Exposure

Oral Exposure/Cadmium Salts. After the patient's airway, breathing, and circulation are secured, attention can be given

to GI decontamination. Although large ingestions of soluble cadmium salts are rare, they frequently prove fatal.^{11,102} The lowest reported human lethal dose is 5 g. In light of this, if a significant ingestion occurs but emesis has not occurred, gastric lavage is appropriate. In this situation, a small nasogastric tube should suffice, as inorganic cadmium salts are powders, not pills.

Given the relative lack of experience with acute oral cadmium poisoning, all patients with known exposures and/or abnormal findings consistent with cadmium toxicity or exposure should be admitted to the hospital for supportive care, monitoring of renal and hepatic function, and possibly evaluation of the GI tract for injury.

Although it seems logical to use chelation therapy in any patient with an acute life-threatening ingestion of a metal compound, the benefit of chelation in acute cadmium exposure is unproven. Multiple chelators have been used, all in animal models, with inconsistent results.

The ideal chelator for treatment of oral cadmium toxicity would be well tolerated, and would decrease GI absorption of cadmium and decrease the concentration of cadmium in organs such as the kidney and liver, while not increasing cadmium concentrations in other critical organs such as the brain. Of the chelators studied for cadmium toxicity, succimer comes closest to fulfilling these criteria. In models of acute oral cadmium toxicity, succimer decreases the GI absorption of cadmium,^{3,6} without increasing cadmium burdens in target organs, and improves survival.^{2,6,50}

In a patient thought to have ingested potentially lethal amounts of cadmium, treatment with succimer is reasonable. Succimer should be given as soon as possible after the ingestion, as the effectiveness of chelators decreases dramatically over time in experimental models of cadmium poisoning.¹⁴

It must be stressed, however, that supporting data for chelation are promising, but not definitive, and are only derived from animal models. Succimer dosing in human cadmium poisoning is unstudied. Doses that are well tolerated (10 mg/kg/dose three times a day) are reasonable.

Other chelators that may be beneficial, but for which further investigation is needed, include diethylenetriaminepentaacetic acid (DTPA)^{6,13} and 2,3-dimercaptopropane sulfonate (DMPS),^{13,50} both of which reduce tissue burdens and increase survival.

Most other chelators are either ineffective or detrimental, including 2,3-dimercaptopropanol (British anti-Lewisite, BAL),^{13,19,49} penicillamine,^{13,62} cyclic tetramines (such as cyclam and tACPD),⁸⁸ detergent formula chelators (such as sodium tripolyphosphate {STPP} and nitrilotriacetic acid {NTA}),^{29,30} CaNa₂EDTA,⁶⁵ and dithiocarbamates.^{3,33}

Pulmonary/Cadmium Fumes. The patient who is ill after exposure to cadmium fumes (generally cadmium oxide) presents with predominantly respiratory complaints and possibly also with constitutional symptoms. The patient's airway should be assessed and appropriate oxygenation ensured, although hypoxia may not be a problem acutely. Steroids are used in most reported cases (although there are no studies to support their efficacy), and a standard dose of methylprednisolone (1 mg/kg up to 60 mg) is reasonable. Because cadmium inhalation injuries are neither benign nor self-limited, all patients with acute inhalational exposures to cadmium should be admitted to the hospital for observation and supportive care until respiratory symptoms have resolved. All such patients should have long-term follow-up arranged with a pulmonologist to assess the possibility of chronic lung injury, even following a single exposure.

Chelation should not be entertained as an option for patients with single acute exposures to cadmium fumes, as these patients do not appear to develop extrapulmonary injury.^{4,5,93,105}

Chronic Exposure

Patients chronically exposed to cadmium frequently come to attention during routine screening, as those who work with cadmium are under close medical surveillance ([Chap. 123](#)). These patients may have developed proteinuria or, less commonly, chronic pulmonary complaints.

Management is challenging. Cessation of cadmium exposure is the first intervention. However, as mentioned earlier, chronic cadmium-induced kidney and lung changes are largely irreversible.

Chelation for chronic cadmium toxicity is not currently recommended. There is no evidence that chelation of chronically poisoned animals improves long term outcomes, and one study in humans found no improvement in cadmium-induced kidney dysfunction with periodic CaNa₂EDTA chelation.¹⁰⁴ Furthermore, in a chronically exposed patient, the majority of cadmium is bound to intracellular metallothionein, which greatly reduces its toxicity. Any attempt to remove cadmium from these deposits risks redistributing cadmium to other organs, possibly exacerbating toxicity, as is known to occur with BAL therapy.²³

Of all the chelators tested thus far in animal models of chronic cadmium toxicity, the dithiocarbamates have shown the most success in reducing total body cadmium burdens. Unfortunately, these chelators tend to cause redistribution of cadmium to the brain; the lipophilicity that allows them to cross cell membranes into hepatocytes (to access stored cadmium) also promotes their uptake into the lipid-rich central nervous system (CNS).³⁴ Numerous dithiocarbamates have been synthesized and studied with regard to cadmium decorporation, however, and several species effectively reduce

whole-body, kidney, and liver cadmium concentrations without an increase in CNS cadmium.^{56,85}

At present, there is insufficient evidence to justify the use of any chelator in the treatment of chronic cadmium toxicity.

SUMMARY

- Cadmium toxicity is largely dependent on route of and chronicity of exposure.
- After acute oral exposure, GI injury predominates.
- After acute inhalation, a severe chemical pneumonitis may ensue.
- With chronic environmental or occupational exposure, nephrotoxicity (usually manifested by proteinuria) is the most significant finding, although other organ systems, such as the lungs, can be affected.
- Treatment for all patients with suspected cadmium poisoning consists of removal from the source, decontamination if possible, and supportive care.
- In the rare instance of exposure from acute cadmium salt ingestion, treatment with succimer may be warranted.
- At this time there is insufficient evidence to recommend chelation in the patient with chronic cadmium poisoning.

92 CESIUM

Zhanna Livshits

Cesium (Cs)	
Atomic number	= 55
Atomic weight	= 132.91 Da
Normal concentrations	
Whole blood	= <10 µg/L (75.42 nmol/L)
Urine	= <20 µg/L (150.48 nmol/L)

HISTORY AND EPIDEMIOLOGY

The name “cesium” derives from Latin word for “sky” (caelum). Gustav Kirchhoff and Robert Bunsen first identified cesium spectrophotometrically in the mineral water of Dürkheim, Germany in 1860.⁸¹ Cesium (Cs) is among the most rare and reactive alkali metals. Elemental cesium (Cs⁰) is silvery white, soft, and malleable. It has a relatively low melting point of 82.4°F (28°C) and thus may exist as both solid and liquid at room temperature. Cs⁰ ignites violently when exposed to moist air or water but forms stable salt complexes. The greatest concentration of naturally occurring cesium (32%), the compound cesium oxide (Cs₂O), is found in the ore pollucite.^{1,78,80} Since Cs⁰ is so highly reactive and short lived, the name “cesium” will refer to cesium salts in the following discussion, unless specifically noted otherwise.

Radionuclides of cesium were identified in the 1940s by the American scientist and Nobel Prize winner Glenn Seaborg and his student Margaret Melhase.⁶⁰ Radioactive cesium isotopes are products of nuclear fission of uranium and plutonium.⁸¹ Both ¹³⁴Cs and ¹³⁷Cs decay via β particle emission; however, only ¹³⁷Cs emits γ rays.⁷⁸ ¹³⁷Cs has a long half-life of 30 years, and it serves not only as an “atomic clock” but also poses potential radiological hazard as it deposits and complexes in earth and water. Of the numerous cesium radioisotopes have been identified to date, only ¹³³Cs is stable.⁹

Several releases of radioactive cesium have occurred in the past century, resulting in large-scale contamination and human exposure. Examples include the nuclear weapons use in Hiroshima and Nagasaki, nuclear weapons testing in Bikini Atoll¹¹ and Republic of Georgia,²⁷ poor nuclear waste management in Goiânia,^{36,57,65} Tammiku,³⁷ and Camp Lilo²⁷ in the Republic of Georgia, as well as critical nuclear power plant malfunctions in Chernobyl⁶⁸ and Fukushima Daiichi.

Whereas nuclear disasters are associated with release of numerous radioactive isotopes, isolated exposure to ¹³⁷Cs was implicated in the events that took place in Goiânia, Tammiku, and Camp Lilo. In September 1987, two men removed a large cylinder that contained ¹³⁷Cs from an abandoned apparatus in Goiânia Institute of Radiotherapy. Several weeks passed between the incident and discovery of the source, with resultant ¹³⁷Cs contamination of the community. Approximately 112,000 people required monitoring and 249 people suffered from internal and external contamination.^{36,65}

On October 21, 1994, three brothers entered a waste repository in Tammiku, Estonia. One of the brothers picked up a metal vessel that unknowingly contained ¹³⁷Cs. Although he died of a syndrome similar to radiation-induced illness, acute radiation contamination was not recognized until his stepson was hospitalized with radiation-induced hand burns a month later.³⁷

Three years later, 11 soldiers undergoing military exercises in Camp Lilo, situated near Tbilisi in the Republic of Georgia, all developed cutaneous radiation syndrome from inadvertent exposure to ¹³⁷Cs capsules at the campsite.²⁷

Occupational exposure to radiocesium occurs routinely in nuclear power plant employees and people who live and work in close proximity to a nuclear facility. Both ¹³⁷Cs and ¹³¹Cs are used as sources of external and internal radiation for treatment of numerous malignancies. Internal radiotherapy with ¹³¹Cs seed implantation, called brachytherapy, is approved by the Food and Drug Administration (FDA).²³ Medical occupational exposure may occur in physicians, patients, and staff working with these isotopes.^{24,58}

Cesium compounds are employed in scintillation counters, photoelectric cells, vacuum tubes, optical instruments, and semiconductors.¹ They serve as catalysts for organic synthesis and are utilized for physiologic laboratory experiments in animal models of ventricular dysrhythmias. Nonradioactive cesium chloride is promoted as a supplement and alternative

treatment for cancer, despite any scientific support for this claim. Its increasing popularity in cancer treatment stems from a theory that cesium chloride increases intracellular pH of tumor cells, resulting in cell death.^{7,70} Cesium chloride was also proposed, but not implemented, as a preventive therapy for potential radiocesium exposure.⁶

PHARMACOLOGY

Like thallium (Chap. 102), cesium has a molecular structure that resembles potassium and similarly, it either mimics or antagonizes potassium in cellular processes.⁴² Since cesium blocks the delayed rectifier (I_{KR}) channel in the cardiac myocyte and prolongs repolarization (Chap. 16), it has been used in animal models to induce QT interval prolongation and subsequent ventricular ectopy and ventricular dysrhythmias.^{54,71}

Although radiocesium is indistinguishable from nonradioactive cesium in biological and chemical reactions, radiocesium damages tissues via emission of β and γ particles during its decay (Chap. 134). ^{134}Cs decays to a stable isotope by emission of β particles. ^{137}Cs initially emits β particles to form the unstable intermediate barium isotope $^{137\text{m}}\text{Ba}$, which then further emits γ rays to form stable ^{137}Ba .¹⁰ Radiocesium is such a potent emitter that lethal doses of radiation are delivered following exposures that are too small to cause cardiac effects.

Pharmacokinetics and Toxicokinetics

Pharmacokinetic data following radiocesium injection and ingestion is derived from radiotracer studies in animals and a few reports in human volunteers. The data are limited and challenging to translate to a human model.

Exposure to cesium occurs through ingestion, inhalation,⁵² injection, and dermal contact. Animal studies with a guinea pig model demonstrate rapid absorption via inhalation, intraperitoneal injection, and ingestion.⁷³ Human volunteer studies demonstrate 98% to 99% absorption of ingested cesium salts.^{66,67} Absorption through intact skin is minimal. One case estimated 20% dermal absorption of radiocesium through burned skin.⁸²

Once absorbed, cesium is rapidly distributed to the blood compartment, followed by subsequent distribution to various organs and eventual accumulation in the skeletal muscle. Animal studies with rat, dog, and guinea pig models demonstrate that cesium is initially distributed to the myocardial, renal, lung, and liver tissue followed by subsequent accumulation in the skeletal muscle.^{41,48,73,77}

Data from human volunteers suggest that once ingested, cesium is absorbed from the small intestine,^{33,42} distributes to the blood compartment and various organs, and eventually accumulates in the skeletal muscle. Volunteer radiotracer studies demonstrate rapid initial accumulation in the liver both following ingestion and injection of radiocesium; and accumulation in the salivary glands following ingestion; subsequent distribution to the myocardium, spleen, adrenals, gastrointestinal (GI) tract, bone, and lungs, with elevated concentration in the skeletal muscle approximately 10 days postexposure.^{35,66} A human biokinetic model suggests that the myocardium, GI tract, and kidneys have the highest extraction ratios of cesium.⁴² Postmortem studies demonstrate elevated concentrations in the skeletal muscle, bone, liver, spleen, and adrenal glands.^{9,46,66}

Cesium undergoes enterohepatic circulation limiting fecal elimination. As such, urinary excretion accounts for 80% to 90% and fecal excretion for 2% to 10% of elimination of an ingested dose.^{44,46,62} Some elimination occurs in the feces independent of whether cesium is injected or ingested, likely due to hepatic elimination.⁶⁶ Only a small amount of cesium is eliminated through sweat or respiratory secretions.^{22,46,83}

Biological elimination $t_{1/2}$ ranges from 50 to 150 days.⁹ Volunteer studies report the biologic elimination half-life of radiocesium from 45 to 150 days,^{32-35,46,49,64,67,79} with few cases up to 200 days³⁵ following ingestion. The biological half-life likely increases with age^{4,8} and male sex⁴ and decreases with pregnancy.⁹⁰ The half-life in children and infants is significantly shorter than that of adults.⁴⁹

^{137}Cs elimination follows first-order kinetics.⁴⁴ Pharmacokinetic analysis in a woman who developed cardiac toxicity from nonradioactive cesium suggested first-order elimination using a two-compartment model.⁸⁸

Radiocesium transfers to placenta and maternal breast milk.^{3,26,31,50,75,86} Modeling based on estimates and human studies demonstrates approximately 0.5%, 10%, and 24% transfer of ^{137}Cs through maternal milk during the stages of early pregnancy, late pregnancy, and lactation.³¹

PATHOPHYSIOLOGY

^{137}Cs undergoes radioactive decay by emission of β particles and γ rays. β Particles have very limited dermal penetration and effects from external exposure are limited to dermal irritation and burns (Chap. 134). Release of β particles within the

body, as typically occurs after inhalation, ingestion, or dermal absorption, may harm internal organs. γ Rays can penetrate the skin with external exposure and cause organ toxicity.

As noted above, cardiotoxicity is the principal and most dangerous clinical effect of nonradioactive cesium. QT prolongation occurs rapidly and predisposes individuals to torsade de pointes (TdP) and ventricular dysrhythmias. In animal models, especially in canines, cesium is one of the more reliable methods to induce and study nonischemic ventricular dysrhythmias. Prolongation of the QT interval in the cardiac myocyte results from antagonism at the delayed rectifier I_{KR} channel.⁸⁹ This delays the repolarization phase of the cardiac action potential, thus prolonging the action potential duration.³⁰ Additionally, it promotes early after-depolarizations (EADs), which are cellular depolarizations that occur during phases 2 and 3 of the cardiac action potential prior to completion of repolarization.^{19,30,43} This generation of EADs is thought to lead to TdP,^{13,19,20,28,74} as cesium chloride-induced EADs precede the development of dysrhythmias in a canine model.^{43,59}

Cesium-induced ventricular dysrhythmias are furthermore potentiated by bradycardia.^{5,38,59} This may be explained by either potentiation of EAD formation³⁸ or increase in temporal variability of the refractory period throughout the cardiac muscle.²⁹ Overdrive pacing abolishes both EADs and ventricular dysrhythmias in an isolated canine cardiac tissue.^{17,43,59} In addition to bradycardia, EADs are induced by hypokalemia²¹ and metabolic acidosis¹² (Chaps. 16 and 17). These EADs are modulated by L-type calcium channel currents,^{2,38} and calcium channel blockers, such as verapamil, suppress cesium-induced ventricular dysrhythmias in dogs.^{16,54}

Sodium channel modulation also may be contributory in cesium-induced ventricular dysrhythmias. Low concentrations of tetrodotoxin, a sodium channel antagonist, terminates EADs induced by cesium chloride.^{5,40} Lidocaine abolishes cesium-induced ventricular dysrhythmias in a canine model.⁵⁴

CLINICAL MANIFESTATIONS

Radiation injuries are discussed in detail in Chap. 134. The following discussion focuses on nonradioactive cesium toxicity.

Cardiovascular Toxicity

Exposure to cesium chloride is associated with QT interval prolongation and predisposes to the development of ventricular dysrhythmias such as TdP. According to case reports, the most common cumulative ingested dose was 3 g/d,^{45,69,87} with only one case reporting 9 g/d.¹⁵ Time from cesium exposure to development of dysrhythmia ranged from 1 week to 3 months. Most patients with ventricular ectopy, TdP, or ventricular dysrhythmias reported a chief complaint of syncope or “seizurelike” activity. Prolonged QT interval was universally present and did not correct with potassium repletion. Serum and urine cesium concentrations were markedly elevated in all case reports. Serum concentrations ranged from 2400 $\mu\text{g/dL}$ ⁵⁶ to 13,973 $\mu\text{g/dL}$ ⁶¹ (reference range, $<10 \mu\text{g/L}$ or $<1 \mu\text{g/dL}$), and urine cesium concentration 750 mg/L ⁸⁷ to 3600 mg/L ⁵⁶ (reference range, $<20 \mu\text{g/L}$). Dalal et al reported whole blood cesium concentration of 160,000 $\mu\text{g/L}$ (reference range, $<10 \mu\text{g/L}$).¹⁵ The QT interval normalized and dysrhythmias ceased after termination of cesium chloride exposure.^{10,14,15,45,56,61,69,87,88}

Intravenous injection of cesium chloride in two end-stage patients with metastatic cancer resulted in death. Forensic records indicate that the first patient had chills and seizures during the first session and went into cardiac arrest during the second session. The second patient collapsed during the infusion.⁹ Postmortem whole blood concentration of cesium was 84.0 $\mu\text{g/mL}$ for first patient and 28.1 $\mu\text{g/mL}$ for second patient (reference range, 0.041–0.138 $\mu\text{g/mL}$ in nonexposed controls). Another case report described an 8 year-old boy who developed bradycardia, premature ventricular depolarizations, and TdP with resultant cardiac arrest that terminated without intervention.¹⁴ Cesium concentrations were not obtained.

Gastrointestinal Effects

Nausea, vomiting, diarrhea, and abdominal cramping are described in case reports of patients ingesting from 3 to 9 g of cesium chloride per day.^{10,15,45,56,69} Although patients experienced GI symptoms during oral therapy with cesium chloride, time course from exposure to onset of symptoms is not described.

Electrolyte Abnormalities

Patients taking cesium chloride supplementation may develop hypokalemia and hypomagnesemia. Serum potassium concentration ranged from 2.8 mEq/L ^{10,61} to 3.2 mmol/L ^{45,69} (reference range, 3.5–5.1 mmol/L), and serum magnesium concentrations were reported as low as 1.4 mg/dL .⁸⁷ Both corrected with electrolyte repletion. Electrolyte imbalance likely

reflects GI loss through vomiting and/or diarrhea.^{10,15,45,61,69,87}

Neurologic Effects

A heightened sense of perception as well as facial and acral tingling are described following self-administration of 6 g of cesium chloride daily for 36 consecutive days.⁵⁵ Reports of syncope^{10,45,56,61,87,88} and “seizures”^{9,15} should be interpreted with caution since a nonperfusing cardiac rhythm is the most likely etiology.

DIAGNOSTIC TESTING

Radioactive cesium may be detected by whole-body counters using γ ray spectrometry and β counting.⁷⁸ Shielding of the room where testing is performed is sometimes necessary to reduce background radiation. Urine and feces may be analyzed for ^{137}Cs and/or ^{134}Cs in a similar manner.

Analysis of nonradioactive cesium in blood, urine, feces, or tissue samples is performed by spectrometric methods such as flame atomic emission spectrometry, inductively coupled plasma mass spectrometry (ICP-MS), or instrumental neutron activation analysis. Cesium concentration following exposure to a nonradioactive cesium salt may also be determined by similar methods such as flame atomic emission spectrometry or ICP-MS.¹

MANAGEMENT

Radiocesium

Patient management following radiation exposure is outlined in detail in [Chap. 134](#) and Antidotes in Depth: A28. Although most data are obtained following radiocesium exposures in both animals and humans, the treatment of patients with cesium-induced toxicity is similar. Recognition and cessation of cesium exposure is critical in all cases of exposure and toxicity.

GI decontamination is likely of limited value and is not recommended following cesium ingestion. Cesium does not adsorb to activated charcoal,⁸⁵ and patients who present with significant cesium toxicity may have vomiting or altered mental status. Administration of antiemetics and repletion of volume loss with intravenous fluids is central to supportive management of patients who present with nausea and vomiting. Serum potassium and magnesium concentrations should be carefully monitored and supplemented as needed.

All patients with suspected cesium salt ingestion should have an electrocardiogram (ECG) and be attached to a continuous cardiac monitor. QT intervals should be monitored closely and documented often with serial ECGs. TdP is an unstable rhythm requiring cardioversion, but recurrent episodes may be prevented with intravenous magnesium infusion and/or overdrive pacing. Cesium chloride-associated cardiac dysrhythmias may be treated with lidocaine and/or synchronous cardioversion. Amiodarone should be used with caution given its propensity to prolong the QT interval.

Since isolated seizures have not been reported, syncope and “seizurelike activity” should heighten concern for hypoperfusion or potential cardiac dysrhythmia.

The following therapies have been attempted after radiocesium exposure and have not been effective: activated charcoal, diuretics, enhanced sweating, and disodium ethylenediaminetetraacetate (EDTA).^{22,84} The paucity of literature makes it challenging to conclusively recommend or reject hemodialysis as a modality for enhanced cesium elimination.^{39,84}

Prussian Blue

Prussian blue, ferric hexacyanoferrate (II), is a blue crystal lattice composed of iron and cyanide molecules. In 2003, the insoluble form of Prussian blue (Radiogardase) was approved by the FDA for oral treatment of thallium and cesium toxicity (Antidotes in Depth: A28).⁶³ The insoluble crystal lattice adsorbs cesium¹⁸ in the intestinal lumen, and enhances both elimination and gut dialysis.⁵³ A systematic analysis of published literature on the use of Prussian blue in the treatment of radiocesium poisoning suggests that it may reduce the half-life of radiocesium by as much as 43%.⁷⁶

Although the majority of Prussian blue literature focuses on radiocesium elimination,^{44,47,51,72,76} there is one case report that described Prussian blue administration in a patient with cesium chloride toxicity. Prussian blue was started on hospital day 7 in a patient with cardiac toxicity following cesium ingestion. She received 3 g three times per day for duration of 4 weeks. Cesium half-life was decreased by 47.7% (from 61.7 days to 29.4 days).¹⁰

Since laboratory confirmation will be substantially delayed, Prussian blue should be administered upon suspicion of cesium toxicity. Although the optimal dose and interval are unknown, the package insert for Radiogardase recommends 3 g orally three times per day, for a total daily dose of 9 g in adults and adolescents. A dose of 1 g orally three times per day is recommended in children for a total daily dose of 3 g. Duration of therapy should be 30 days.⁶³

SUMMARY

- Radioactive cesium is a strong β - and γ -ray emitter that is released following normal operation of power plants and/or nuclear incidents.
- Because of the availability of commercial and therapeutic sources of radioactive cesium, human exposure is also likely either through unintentional exposure to discarded equipment or through acts of terrorism.
- Exposure to nonradioactive cesium salts occurs through intentional use as an alternative therapy for cancer.
- The principal toxicity of nonradioactive cesium is ventricular dysrhythmias and TdP that result from blockade of cardiac potassium channels.
- In addition to supportive care, Prussian blue is indicated for both radioactive and nonradioactive cesium toxicity.

93 CHROMIUM

Steven B. Bird

Chromium (Cr)	
Atomic number	= 24
Atomic weight	= 51.99 Da
Normal concentrations	
Whole blood	= 20–30 µg/L (380–580 nmol/L)
Serum	= 0.05–2.86 µg/L (1–56 nmol/L)
Urine	< 1 µg/g creatinine (19.2 nmol/g creatinine)

HISTORY AND EPIDEMIOLOGY

Chromium (from the Greek word for color, chroma) is a naturally occurring element that may be found in oxidation states of –2 to +6 but primarily exists in the trivalent (Cr^{3+}) and hexavalent (Cr^{6+}) forms. It was first discovered in 1797 in the form of Siberian red lead (crocoite: PbCrO_4), and it occurs only in combination with other elements, primarily as halides, oxides, or sulfides (Table 93–1).

TABLE 93–1. Common Forms of Chromium

Name	Chemical Formula	Oxidation State	Uses
Barium chromate	BaCrH_2O_4	6+	Safety matches, anticorrosive, paint pigment
Calcium chromate	CaCrO_4	6+	Batteries, metallurgy
Chromic acid	H_2CrO_4	6+	Electroplating, oxidizer
Chromic chloride	CrCl_3	3+	Supplement in total parenteral nutrition
Chromic fluoride	CrF_3	3+	Mordant in dye industry, moth-proofing agent for wool
Chromic oxide	Cr_2O_3	3+	Metal plating, wood treatment
Chromite ore	FeCr_2O_4	3+	Water tower treatment
Chromium picolinate	$\text{C}_{18}\text{H}_{12}\text{CrN}_3\text{O}_6$	3+	Nutritional
Lead chromate	PbCrO_4	6+	Yellow pigment for paints and dyes
Potassium dichromate	$\text{K}_2\text{Cr}_2\text{O}_7$	6+	Oxidizer of organic compounds, leather tanning, porcelain painting

Elemental chromium (Cr^0) does not occur naturally but is extracted commercially from ore. Chromium is found most abundantly in chromite ore (FeCr_2O_4).⁹ Elemental chromium is a blue-white metal that is hard and brittle. It can be polished to a fine, shiny surface, affords significant protection against corrosion, and can be added to steel in order to form stainless steel (an alloy of chromium, nickel, and iron). One of the most important uses of chrome plating is to apply a hard, smooth surface to machine parts such as crankshafts, printing rollers, ball bearings, and cutting tools. This is known as “hard” chrome plating. Elemental chromium is also used in armor plating, safes, and is used in forming brick molds due to its high melting point and limited thermal expansion.

The carcinogenic potential of hexavalent chromium was first recognized as a cause of nasal tumors in Scottish chrome pigment workers in the late 1800s. In the 1930s, the pulmonary carcinogenicity of hexavalent chromium was first described in German chromate workers.¹³ Chromium toxicity may result from occupational exposure, environmental exposure, or a combination of both routes. Like many metals, the clinical manifestations of chromium toxicity depend upon whether the exposure is acute or chronic and on the chemical form of chromium.

PHARMACOLOGY

Chromium is an essential element involved in glucose metabolism. This may be through facilitation of insulin binding to insulin receptors or by amplification of the effects of insulin on carbohydrate and lipid metabolism. Chromium deficiency may have a causal link to diabetes mellitus and arteriosclerosis. Cr³⁺ is an essential trace metal required for the metabolism of glucose and fats. The complex nutritional interactions of trivalent chromium with numerous metabolic pathways are not understood and remain the subject of much debate among researchers. However, it is clear that dietary chromium deficiency leads to elevated insulin concentrations, hypercholesterolemia, hyperglycemia, increased body fat, and the attendant risks of these metabolic derangements. Cr³⁺ enhances insulin sensitivity and glucose disappearance concomitantly with lower insulin concentrations in a obese rat models, with no difference in lean controls.¹²

The chemical properties and health risks of chromium depend mostly on its oxidative state and on the solubility of the chromium compound. Chromium in the Cr⁶⁺ and Cr³⁺ oxidation states has very different properties. The relationship between these oxidative states is described by the following equation:

This difference of 1.33 eV in electric potential between the Cr⁶⁺ (in Cr₂O₇²⁻) and Cr³⁺ states reflects both the significant oxidizing potential of Cr⁶⁺ and the high energy required for the oxidation of Cr³⁺ to Cr⁶⁺. Reduction of Cr⁶⁺ to Cr³⁺ occurs in vivo by abstraction of electrons from cellular constituents such as proteins, lipids, DNA, RNA, and plasma transferrin and accounts for the toxicity of Cr⁶⁺.³⁷

The rapidity and completeness of the reduction of Cr⁶⁺ is the subject of considerable scientific debate. Hexavalent chromium is reduced to Cr³⁺ in saliva, the gastrointestinal tract, the respiratory tract epithelium and pulmonary macrophages, and in blood.^{4,34} During this reduction, several other oxidative states transiently occur (namely Cr⁴⁺ and Cr⁵⁺) and contribute to the cytotoxicity, genotoxicity, and carcinogenicity of Cr⁶⁺ chromium compounds.⁴⁶

Although most Cr⁶⁺ is rapidly reduced upon entering the stomach before it can be absorbed, ingestion of Cr⁶⁺ in drinking water does lead to measurable Cr⁶⁺ concentrations in plasma, red blood cells, and urine. Hexavalent chromium can accumulate in most body tissues, raising concerns that chromium-induced toxicity and carcinogenesis may be more widespread than is currently appreciated.¹³

Environmental Exposure

The processing of chromium ores primarily releases Cr³⁺ into the environment. However, some hexavalent chromium is released from chromate manufacturing and coal-based power plants. The most significant environmental sources of Cr⁶⁺ are chromate production, ferrochrome pigment manufacturing, chrome plating, and certain types of welding.

The general population may be exposed to chromium via drinking water, food and food supplements (eg, chromium picolinate), joint arthroplasty, coronary artery stents, and cigarettes. Hexavalent chromium salts are used extensively to prevent equipment and piping corrosion in industrial cooling towers and air conditioning and malfunctions or corrosion may lead to cross contamination with drinking water. Dermal exposure may occur from use of tanned leather products or wood treated with copper, chromate, and arsenate (CCA), which contains hexavalent chromium. This form of chromium is reduced to trivalent chromium by natural organic compounds found in wood. CCA-treated lumber was voluntarily removed from the US consumer market in December 2003 because of possible health concerns as a result of exposure to the arsenic and chromium. No specific adverse health effects related to CCA-treated lumber were reported by the Environmental Protection Agency prior to the voluntary withdrawal. A recent reanalysis of cancer mortality and hexavalent chromium-contaminated drinking water from Liaoning Province, China, demonstrated an increase in stomach cancer rate in communities with chromium-contaminated drinking water from ferrochromium factories.⁷ Significant exposure from more than 160 chromate production waste sites within Hudson County, New Jersey was discovered in the late 1980s.²⁰ A final report published by the Agency for Toxic Substances and Disease Registry in 2008 found an increased risk of lung cancer incidence in populations living in close proximity to historic chromium ore processing residue sites, although the increases were not statistically significant.²

Occupational Exposure

Workers in industries that use chromium may be exposed to 100 times greater concentrations of chromium than the general population. Chromium pigmentation production and leather tanning use significantly more Cr^{6+} compounds, whereas metal finishing and wood preservation use Cr^{3+} compounds (Table 93–2).

TABLE 93–2. Occupations at Risk for Chromium Exposure

Cement workers
Chromite ore workers
Electroplaters
Foundry workers
Galvanized steel workers
Glass polishers and glazers
Lithographers
Machinists
Painters

Wood preservers

Several studies have focused on the risk of chromium exposure in welders.^{41,42} Stainless steel welding liberates significantly more hexavalent chromium than do other types of welding. Although the lung cancer rate of chromium containing stainless steel welders does not differ from that of regular steel welders, in 2006 the Occupational Safety and Health Administration (OSHA) lowered the permissive exposure limit of hexavalent chromium by 10-fold for welders.

Medical Device Exposure

Ongoing concerns and media attention have been directed to the use of metal-on-metal (MoM) implants for total hip arthroplasty and surface refinishing. Unlike non-MoM implants made of ceramic or polyethylene, these metal implants contain chromium and cobalt. As early as 1997, it was demonstrated that blood concentrations of metal ions increase in patients with MoM hip arthroplasty.¹⁰ One-year postoperative blood chromium concentrations increased by 21 times over the preoperative concentrations in patients with MoM implants.²³ Metal release will cause some tiny metal particles to wear off the device around the implant, which may damage to bone and/or soft tissue surrounding the implant and joint. Although some patients with failed MoM hip implants have complained of memory difficulties, chronic pain, and pain in the implanted hip, the true incidence and nature of adverse health outcomes due to release of chromium ions and particles from these implants has not yet been established. Currently, there is insufficient evidence to conclusively demonstrate that MoM hip implants produce side effects beyond those that may occur at the site of implantation. The significance of elevated blood chromium concentrations is unknown.¹⁹ (See Chap. 94 for further discussion of arthroprosthetic cobaltism.)

PHARMACOKINETICS AND TOXICOKINETICS

Because they possess significantly different properties, Cr^{3+} and Cr^{6+} must be evaluated separately.

Absorption

Trivalent Chromium Compounds. Oral absorption of Cr^{3+} salts is limited. Approximately 98% of an ingested dose is recovered in the feces, just 0.1% is excreted in the bile, and 0.5% to 2.0% is excreted in the urine.^{17,33} Human case reports and animal studies also corroborate the generally poor absorption of Cr^{3+} salts by the oral, inhalational, and dermal routes, except through burns and other disrupted mucosal or epithelial surfaces.²⁹

Hexavalent Chromium Compounds. Cr^{6+} is modestly absorbed after ingestion partly as a result of the structural similarity between hexavalent chromium compounds and phosphate and sulfate.¹⁴ These three chemicals undergo both facilitated diffusion through nonspecific anion channels and active transport. In human volunteers, approximately 10% of an orally ingested dose of sodium chromate was absorbed; duodenal administration increased this to roughly 50%.¹⁷ This difference likely relates to the reduction of the hexavalent chromium to trivalent chromium in the acidic environment of the

stomach. Similarly, 3 hours after a lethal ingestion of potassium dichromate (hexavalent), greater than 80% of the chromium was reduced to the trivalent state in the blood.²² Hexavalent chromium compounds are generally not well absorbed after dermal exposure. Whatever the route of exposure, Cr^{6+} is absorbed much more readily than Cr^{3+} , but the Cr^{6+} is then rapidly reduced to Cr^{3+} after absorption.

Epidemiologically, inhalational of Cr^{6+} is the most consequential route of exposure. However, the greatest health consequences from Cr^{6+} exposure are due to inhalation. The exact rate of absorption is unknown but is dependent on the solubility of the specific Cr^{6+} compound, the size of the particles, the phagocytic activity of the pulmonary macrophages, and general health of the lungs. Animal studies suggest that roughly 50% to 85% of small ($<5\ \mu\text{m}$) Cr^{6+} potassium dichromate particles are absorbed.²

Distribution

Because most of the Cr^{6+} is rapidly reduced before absorption by the stomach, proximal gastrointestinal tract, and by red blood cells (RBCs), Cr^{3+} accounts for virtually the entire body burden of chromium. Trivalent chromium accumulates to the greatest extent in the kidneys, bone marrow, lungs, lymph nodes, liver, spleen, and testes. The kidneys and liver alone account for approximately 50% of the total body burden.¹⁴

Elimination

Urinary excretion of trivalent chromium occurs rapidly. Roughly 80% of parenterally administered Cr^{6+} is excreted as Cr^{3+} in the urine and 2% to 20% in the feces.³³ The urinary excretion half-life of Cr^{6+} ranges from 15 to 41 hours.²⁴ Because Cr^{6+} undergoes reduction to Cr^{3+} following uptake by RBCs, an apparent slow compartment is created, with the elimination half-life dependent on the life span of RBCs. Small amounts of chromium are detectable in sweat, breast milk, nails, and hair.

PATHOPHYSIOLOGY

Trivalent Chromium

Chromium picolinate is a popular Cr^{3+} dietary supplement. There is a dearth of rigorous science concerning the efficacy or safety of chromium picolinate. However, it appears that organ deposition of Cr^{3+} occurs.⁴⁰ There is no strong evidence of any significant end-organ toxicity due to exposure to Cr^{3+} , perhaps because Cr^{3+} is so poorly absorbed. There is little or no rigorous evidence that exposure to Cr^{3+} compounds increases cancer risk. Animal work and epidemiological studies of workers exposed to Cr^{3+} compounds have failed to demonstrate a statistically significant increased incidence of cancer.⁵

Hexavalent Chromium

Cr^{6+} is a powerful oxidizing agent that has corrosive and irritant effects. The greatest toxicity from Cr^{6+} lies in its ability to produce oxidative DNA damage. DNA strand breaks, DNA-DNA and DNA-protein cross-links, and nucleotide modifications all occur.¹⁵ Although the exact mechanisms of how Cr^{6+} affects the genome are unknown, transient toxic chromium intermediates such as Cr^{4+} and Cr^{5+} are probably responsible.³⁹

Inconsistent data suggest that either immunostimulation and immunosuppression result from chronic chromium exposure. At least one study suggests that chromium-induced immunosuppression may be responsible for implant-associated infections in patients after hip or knee arthroplasty.⁴⁷ In limited human studies, no adverse developmental toxicity has been demonstrated. In animals, adverse developmental effects, including cleft palate, hydrocephalus, and neural tube defects, are described.¹⁶

CLINICAL MANIFESTATIONS

The clinical manifestations of chromium poisoning depend on the valence of the element, the source and route of exposure, and the duration of exposure. The clinical manifestations of chromium exposure are best divided into acute and chronic (low-level exposure) effects.

Acute

Manifestations of acute, massive Cr^{6+} ingestions are similar to other corrosive metal ingestions. Gastrointestinal hemorrhage, with or without bowel perforation, may occur acutely.⁵⁰ Because of the strong oxidative properties of Cr^{6+} ,

intravascular hemolysis with disseminated intravascular coagulation may also develop. Renal effects include acute tubular necrosis leading to acute kidney injury.⁴⁹ Metabolic abnormalities after acute, massive exposure include lactic acidosis, hyperkalemia, and uremia. Acute respiratory distress syndrome may develop up to 3 days after exposure. Although Cr^{6+} is generally not well absorbed after dermal exposure, it is a corrosive that causes skin inflammation and ulceration, which can lead to increased dermal absorption. Dermal chromic acid (H_2CrO_4) burns may lead to severe systemic toxicity with as little as 10% body surface area involvement.

Chronic

Because most chronic exposures are inhalational, the respiratory tract is the organ most affected after chronic chromium exposure. When inhaled, Cr^{6+} is a respiratory tract irritant that causes inflammation and, with continued exposure, ulceration (including nasal septum perforation).²⁵ Furthermore, the sensitizing effects of Cr^{6+} may lead to chronic cough, shortness of breath, occupational asthma, bronchospasm, and anaphylactoidlike reactions. Chronic deposition of chromium dust may also lead to pneumoconiosis.³⁸

Epidemiological studies of chromate workers in the 1980s indicated a significantly increased risk of lung cancer in individuals exposed to Cr^{6+} compounds.^{26,35} Small-cell and poorly differentiated carcinomas are the most common types, although nearly all pathologic types of lung cancer are associated with inhalational Cr^{6+} exposure.¹ The latency between exposure and development of lung cancer ranges from 13 to 30 years, although cases have been reported after as few as 2 years.⁸

Although conclusive evidence is missing, it appears that chronic exposure to Cr^{6+} via all routes may cause mild-to-moderate elevation in hepatic aminotransferases and abnormal liver architecture, visible on histologic specimens.⁵⁰ Unlike acute exposures, low-dose chronic chromium exposure occasionally causes only transiently elevated urinary β -microglobulin concentrations, with no obvious lasting effects.⁴⁹

Type IV (delayed-type) hypersensitivity reactions may occur after acute exposure to hexavalent chromium compounds. Chronic hexavalent chromium exposures also occur via dermal contact. Up to 24% of cement workers who have frequent contact with wet cement (which contains Cr^{6+}), automobile part handlers, and locksmiths develop skin sensitivity to chromium compounds.^{28,30}

Occupational chromium exposure may also lead to contact dermatitis (dermatitis toxicosis) in as many as 10% to 20% of chromium workers.⁴⁴ There remains considerable debate over the relative sensitization abilities of Cr^{3+} and Cr^{6+} . Furthermore, what was initially thought to be sensitization to Cr^{3+} exposure may in fact have been exposure to Cr^{6+} with subsequent in vivo reduction to Cr^{3+} . It appears, however, that the Cr^{6+} is a more potent sensitizer than Cr^{3+} and that there may be limited cross-reactivity between the two forms of chromium.¹⁸ Similarly, chromium-containing gaming table felt has led to hand dermatitis referred to as “blackjack disease,” and virtually all occupations that involve exposure to chromium can lead to painless skin and nasal septum ulcerations referred to as “chrome holes.”²⁷

DIAGNOSTIC TESTING

Chromium may be detected in blood, urine, and hair of exposed individuals. Because of the great difficulty in speciation, differentiation between Cr^{3+} and Cr^{6+} is generally not performed; instead the total chromium concentration is usually reported. Needles used for phlebotomy and plastic containers used for sample storage may all contain significant amounts of chromium. Unfortunately, there are no commercially available chromium-free needles. Modern, highly sensitive assay equipment such as graphite furnace atomic absorption spectrometry, neutron activation analysis, and graphite spark atomic emission spectrometry requires diligence in sample handling to ensure that biological samples are not contaminated.

Because of the inherent difficulties in quantifying trace elements such as chromium, and the lack of standard chromium reference materials, the reported normal serum and urine chromium concentrations in unexposed people have varied by more than 5000-fold over the past 50 years.³ Consequently, older reference ranges should be interpreted with caution. Lastly, although cigarette smoke contains chromium, no studies have quantified the effect of smoking on serum, blood, or urinary chromium concentrations.

Blood or Serum

Chromium is distributed evenly between the serum and erythrocytes. Serum chromium concentrations are reflective of recent exposure to both Cr^{3+} and Cr^{6+} . Serum concentrations in people without occupational exposure to chromium range from 0.05 $\mu\text{g/L}$ (1 nmol/L)¹¹ up to more than 2.8 $\mu\text{g/L}$ (56 nmol/L).³ It is not certain whether concentrations above these values should be considered potentially toxic, as no clear correlation has been found between serum or blood concentrations and physiologic effects.

Urine

Although urine chromium concentrations reflect the acute absorption of chromium over the previous 1 to 2 days, wide individual variation in metabolism and total body burden limit the value of urinary chromium monitoring. Urine should be collected in acid-washed plastic (polypropylene) containers over a 24-hour period due to diurnal variation in excretion. Data from the third National Health and Nutrition Examination Survey (NHANES III) demonstrated mean and median urinary chromium concentrations in approximately 500 individuals without known exposure to chromium of 0.22 µg/L (4.4 nmol/L) and 0.13 µg/L (2.6 nmol/L). When corrected for creatinine, the values were 0.21 and 0.12 µg/g creatinine, respectively.³²

Hair and Nails

Hair and nail samples are not reliable indicators of exposure to chromium because of the difficulty distinguishing between chromium contamination of the hair sample from chromium incorporated into the hair during normal hair protein synthesis. Chromium found in hair is not due to contamination or exposure to shampoo or tap water.²¹ Chromium concentrations in hair may be up to 1000 times higher than those found in serum.

Ancillary Tests

After confirmed or suspected acute chromium exposure, complete blood count, serum electrolytes, blood urea nitrogen, creatinine, urinalysis, and liver enzymes testing should be performed. If signs of systemic toxicity are evident, serial determination of coagulation function and disseminated intravascular coagulation may be useful to guide therapy.

MANAGEMENT

Patients with acute chromium ingestions are infrequent but often become severely ill, with significant morbidity and mortality. Consequently, after adequate airway, breathing, and circulatory support have been addressed, attention should be given to decontamination.

Decontamination

As a consequence of its very limited toxicity, Cr³⁺ compounds should require limited decontamination measures. However, as coingestants could be present, standard gut decontamination with activated charcoal should be considered as clinically indicated. Like with most other dermal exposures, decontamination with soap and water should be performed after skin contact. No specific pulmonary decontamination is required.

Hexavalent chromium is corrosive, and profuse vomiting and hematemesis usually follow acute ingestions. Nasogastric lavage may be beneficial after Cr⁶⁺ ingestions if the patient presents to the emergency department within 1 to 2 hours of exposure and no vomiting has occurred. There are no data regarding the use of activated charcoal in acute chromium ingestions. Endoscopic visualization may be difficult after administration of activated charcoal, and the relative benefits of these two modalities need to be considered. If there is a low likelihood of a coingestion, it is better to forego activated charcoal in order to obtain adequate endoscopic visualization. Known or suspected perforation is an absolute contraindication to activated charcoal.

Oral N-acetylcysteine increases the renal excretion of chromium in rats,⁶ but there are no human data to support this therapy. Years of clinical experience using N-acetylcysteine for other indications and the very low incidence of adverse effects, however, favor the administration of oral N-acetylcysteine in the setting of acute chromium toxicity.

Although ascorbic acid facilitates reduction of Cr⁶⁺ to Cr³⁺ in vitro, there are no data to substantiate decreased absorption.⁴⁴ There is some evidence that topical ascorbic acid may reduce dermal Cr⁶⁺ exposure, but this has not been demonstrated in controlled trials.³⁹ Therefore, the routine use of ascorbic acid cannot be advocated at this time.

Chelation Therapy

Currently available chelating agents do not appear efficacious at either lowering serum or blood chromium concentrations or ameliorating chromium toxicity in experimental models. Specifically, ethylenediaminetetraacetic acid (EDTA) has no effect on urinary chromium excretion in human subjects,⁴⁸ and dimercaprol (British anti-Lewisite, BAL) was not beneficial in an animal model of chromium poisoning.³¹

In a single study, dimercaptopropane sulfonate (DMPS) had no effect on urinary chromium excretion in humans.⁴⁵ D-Penicillamine also failed to increase urinary excretion of chromium.³¹ There are no studies of chromium chelation with 2,3-dimercaptosuccinic acid (succimer). Therefore, at this time, there is no evidence to support the use of chelation therapy after acute Cr⁶⁺ or Cr³⁺ poisoning.

Extracorporeal Elimination

Hemodialysis, hemofiltration, and peritoneal dialysis do not efficiently remove chromium. Studies in animals and human case reports indicate that as little as 1% of chromium is removed by hemodialysis or hemofiltration after acute dichromate (a hexavalent compound) exposure.^{22,43} Exchange transfusions may rapidly reduce blood chromium concentrations, but there are no data suggesting that clinical outcomes are positively affected. Limited data in dialysis patients have demonstrated some ability of peritoneal dialysis and hemodialysis to remove intravenously administered chromium.³⁶ Therefore, in the setting of normal kidney function, extracorporeal means of eliminated chromium are not likely to be of benefit. In the setting of acute or chronic kidney failure, peritoneal dialysis or hemodialysis may be beneficial in reducing serum chromium concentrations, although there are no data that clinical outcomes are affected.

SUMMARY

- Hexavalent (Cr^{6+}) chromium remains an uncommon but serious cause of acute metal salt poisoning, while trivalent (Cr^{3+}) chromium lacks toxicity.
- The acute exposure to Cr^{6+} chromium salts by ingestion causes gastrointestinal hemorrhage, hepatic necrosis, and acute kidney injury.
- Chronic Cr^{6+} chromium exposure includes ulcerations of the skin and nasopharynx (“chrome holes”), and more significantly, lung and stomach cancer.
- Regardless of the time course of the poisoning, treatment for chromium exposure includes removal of the patient from the source of exposure, gastrointestinal decontamination, and supportive care. There is insufficient evidence to support the use of chelators in either acute or chronic chromium poisoning.

94 COBALT

Gar Ming Chan

Cobalt (Co)	
Atomic number	= 27
Atomic weight	= 58.9 Da
Normal concentrations	
Serum	= 0.1–1.2 µg/L (1.7–20.4 nmol/L)
Urine	= 0.1–2.2 µg/L (1.7–37.3 nmol/L)

HISTORY AND EPIDEMIOLOGY

The name cobalt (Co) originates from kobold, German for “goblin,” and was given to the cobalt containing ore, cobaltite (CoAsS), because it made exposed miners ill. However, the miners’ illness was more likely a result of exposure to arsenic rather than cobalt. Brandt discovered cobalt in 1753 during an attempt to prove that an element other than bismuth gave glass a blue hue.

With an atomic number of 27 and a molecular weight of 58.93 Da, cobalt is a light metal with a melting point of 1768.2°K and a boiling point of 3373°K. These attributes make elemental cobalt (Co⁰) very useful in industry, where it is primarily incorporated into hard, high-speed, high-temperature cutting tools. When aluminum and nickel are blended with cobalt, an alloy (Alnico) with magnetic properties is formed. Other uses for cobalt include electroplating because of its resistance to oxidation and as an artist’s pigment due to its bright blue color.

A Co³⁺ ion is at the center of cyanocobalamin (vitamin B₁₂), which is synthesized only by microorganisms and is not found in plants. Common dietary sources are fish, eggs, chicken, pork, and seafood. A diet deficient in cyanocobalamin results in pernicious anemia. Hydroxocobalamin, a Co³⁺ containing precursor to cyanocobalamin, is used as an antidote for cyanide poisoning (Antidotes in Depth: A41).

Medicinally, cobalt chloride was combined with iron salts and marketed in the 1950s as “Roncovite”—for the treatment of anemia due to its ability to stimulate erythropoiesis. As recently as 1976, physicians still used cobalt salts to reduce transfusion requirements in anemic patients, despite well-known adverse effects.⁴³ The other common medical use of cobalt is as a radioactive isotope, cobalt-60 (⁶⁰Co). This γ emitter was formerly used in the radiotherapy of cancers but has been largely replaced by linear accelerators in the Western world. Radiotherapy machines may be targeted by terrorist groups as a source of radioactive material.

Epidemics of cardiomyopathy and goiter termed “beer drinker’s cardiomyopathy”¹⁶ and “cobalt-induced goiter”⁶⁹ occurred between the 1960s and the 1970s. During this period, cobalt sulfate was added to beer as a foam stabilizer. In the 1970s, these epidemics were halted with the discontinued use of cobalt sulfate for this purely esthetic purpose.¹⁰⁶

Current sources of cobalt exposure include chemistry kits,⁷⁴ weather indicators,⁷⁴ antiquated anemia therapies,⁷⁴ cement,⁸¹ fly ash,⁸¹ dyes,⁵³ mineral wool,⁸¹ asbestos,⁸¹ molds for ceramic tiles,⁴⁹ the production of Widia-steel (utilized in the wood industry),¹⁴² mining,⁷⁵ porcelain paint,¹²⁶ orthopedic implants,⁷³ and dental hardware.⁷ A recent area of attention is “arthroprosthetic cobaltism,”^{97,115,130,156,157} which results from cobalt-containing orthopedic implants.¹⁵⁸

The most significant source, however, arises through the formation of cemented tungsten carbide, a “hard metal.” In tungsten carbide factories, powdered cobalt and tungsten are combined through an intense sintering process that exposes the metals to hydrogen that has been heated to 1832°F (1000°C). The first published investigation of these factories reported a 10-fold increase in workspace cobalt concentrations compared to atmospheric concentrations.⁴⁶ These respiratory exposures result in pulmonary toxicity, known as “hard metal disease.” As a result of the original report, occupational studies and preventive measures have greatly reduced the acceptable cobalt exposure concentration in the workplace.

CHEMISTRY

Like other metals, cobalt occurs in elemental, inorganic, and organic forms. The clinical effects of each form are less well defined than more common transition metals such as lead, mercury, or arsenic. Elemental cobalt (Co^0) toxicity is reported through both inhalational¹⁵⁵ and oral exposures.^{68,69} Inorganic cobalt salts typically occur in one of two oxidation states: cobaltous (Co^{2+}) or cobaltic (Co^{3+}). Inorganic cobalt salts, such as cobaltous chloride (CoCl_2) and cobaltous sulfate (CoSO_4), were historically used for the treatment of anemias^{17,58,64,125,166} and were implicated in the “beer drinker’s cardiomyopathy” epidemics, respectively.^{2,101,108}

Organic cobalt exposure results from cyanocobalamin (vitamin B_{12}) ingestion, but due to its limited oral absorption and its rapid renal elimination it is considered of low toxicity.¹²² Comparing organic and inorganic forms of cobalt in animal models, cobalt salts are more toxic than the organic forms such as cobalt stearate.²¹

TOXICOKINETICS

Based on animal studies, oral absorption of cobalt oxides, salts, and metal is highly variable with a reported bioavailability of 5% to 45%.^{82,93} In human studies, both iron deficiency and iron overload (hemochromatosis) enhance radiolabeled ⁵⁷ CoCl_2 absorption in the small bowel.¹¹⁴ Similarly, inhaled cobalt oxide is about 30% bioavailable,⁹³ but the volume of distribution and elimination half-life are not well defined.

The distribution of cobalt is influenced by plasma proteins, mainly albumin^{22,23} and is the basis of the recently Food and Drug Administration (FDA)–approved albumin cobalt binding test (ACB test) for myocardial ischemia. Transferrin, another plasma protein, which normally binds iron can also bind cobalt and may help explain its erythropoietic effect.⁷⁶ Following distribution, cellular uptake is mediated by P2X7 transporter¹⁶⁰ and the active divalent metal transporter 1 (DMT1).²³

Most (50%–88%) absorbed cobalt (organic and inorganic) is eliminated renally, and the remainder is eliminated in the feces.¹⁴⁰ Acutely, an increase in inorganic cobalt concentrations will result in an increased renal elimination.⁷⁹ However, this initial increased elimination decreases rapidly in spite of a large body burden.^{3,114}

The elimination of cobalt correlates with the patterns of occupational exposure.¹⁵⁵ For example, a worker with a standard work week will have much higher urine cobalt concentrations on Friday morning compared to Monday morning.¹⁵⁵ However, Monday afternoon urine cobalt concentrations may be higher than Friday morning concentrations, which is due to the rapid elimination that occurs following an initial exposure.^{3,155} Based on these findings, the exposure over time must be considered when interpreting urinary cobalt concentrations in occupationally exposed individuals.¹²

PATHOPHYSIOLOGY

Like other transition metals, cobalt is a multiorgan toxin. Co^{2+} inhibits several key enzyme systems and interferes with the initiation of protein synthesis.¹³ Polynucleotide phosphorylase, an essential enzyme in RNA synthesis, requires Mg^{2+} to function normally. In vitro, this enzyme only functions at 50% that of normal in the presence of Co^{2+} .¹³ It is hypothesized that Co^{2+} is capable of displacing Mg^{2+} from its cofactor site of this enzyme.¹³

Cobalt salts interfere with the Krebs cycle mitochondrial enzyme, α -ketoglutarate dehydrogenase. Due to this inhibition, Co^{2+} increases the rate of anaerobic glycolysis and at the same time decreases oxygen consumption³¹ and thus inhibits aerobic metabolism. In vitro studies demonstrate that other divalent cations, Zn^{2+} , Cd^{2+} , Cu^{2+} , and Ni^{2+} , also inhibit α -ketoglutarate dehydrogenase (Chap. 13).¹⁶³ When compared to these other divalent cations, Co^{2+} is not considered a potent inhibitor.¹⁶³ However, this in vitro model demonstrates that Co^{2+} is capable of almost entirely inhibiting the reaction when nicotinamide adenine dinucleotide (NADH) is added.¹⁶³ This study suggests that NADH abundance, such as occurs with chronic ethanol use, may potentiate the inhibition of α -ketoglutarate dehydrogenase.¹⁶⁴

Moreover, cobalt salts are capable of inhibiting α lipoic acid and dihydrolipoic acid by complexing with its sulfhydryl groups.^{34,163} These reactions result in the inability to convert both pyruvate into acetyl-CoA and α -ketoglutarate into succinyl-CoA (Chap. 13 and Antidotes in Depth: A24). These combined interactions may explain why chronic ethanol use and cobalt exposure result in cardiomyopathy (see Clinical Manifestations, Cardiovascular).¹⁶³

In addition to enzyme inhibition, CoCl_2 induces oxidant-mediated pulmonary toxicity (see Clinical Manifestations, Pulmonary)¹¹² and neurotoxicity.²³ Xenobiotics implicated in free radical–mediated pulmonary injury are capable of accepting an electron from a reductant and subsequently transferring the electron to oxygen, forming a superoxide free radical (Chap. 12). Cobalt is then capable of accepting another electron, which starts the cycle over again, a process known as redox cycling. This leads to an accumulation of free radicals in the lung due to the abundance of oxygen ready to receive electrons and results in injury.

Within the endocrine system, CoCl_2 is capable of inhibiting tyrosine iodinase.⁸⁵ This enzyme is responsible for combining iodine (I_2) with tyrosine to form monoiodotyrosine and serves as the first step in the synthesis of thyroid hormone (Chap. 56). Inhibition of tyrosine iodinase leads in a decrease of circulating T_3 and T_4 which may result in hypothyroidism (see Clinical Manifestations, Endocrine).

The hematopoietic system is also affected by cobalt salts. Multiple animal models demonstrate that CoCl_2 administration results in reticulocytosis, polycythemia, and erythropoiesis.^{52,83,105,116,117,166} These events occur in both the bone marrow and extramedullary locations.^{17,55} Although the pathogenesis remains largely unknown,³⁴ one theory is that cobalt ion binds to iron binding sites such as transferrin,⁷⁶ resulting in impaired oxygen transport to renal cells, which in turn induces erythropoietin production. A second theory in which cobalt is thought to stimulate erythropoiesis is through improving iron availability. In an animal model of anemia, a greater degree of gastrointestinal iron uptake occurs in cobalt-treated rats compared to rats with either hypoxia or nephrectomy.⁵⁵ A similar study of injected cobalt chloride in mice suggested that the increase in iron uptake exceeded that following exogenous erythropoietin.⁴

Finally, within the nervous system, CoCl_2 inhibits neuromuscular transmission by competing with Ca^{2+} , another divalent ion. Co^{2+} is 20 times more potent than magnesium with regard to its ability to compete with calcium for a site on the motor nerve terminal.¹⁶² Additionally, the formation of free radicals is theorized as a cause of cobalt associated neurotoxicity.²³

TOXICITY

The single acute minimal toxic dose of cobalt salts is not well defined. In fact, varying effects have occurred at variable doses in different patients. Patients with “beer drinker’s cardiomyopathy” received an average daily dose of 6 to 8 mg of CoSO_4 (over weeks to months) and developed toxic effects of acidemia, cardiomyopathy, shock, and death,^{80,108} whereas infants being treated for anemia who received much higher daily cobalt doses of an iron-cobalt preparation (40 mg of CoCl_2 and 75 mg of FeSO_4) for 3 months did not develop toxicity.¹³¹ The inconsistency of these findings suggests that multiple factors are responsible for the development of the clinical manifestations of toxicity; in this case the role of ethanol metabolism may be an important variable.⁷⁴

CLINICAL MANIFESTATIONS

Organ systems affected by acute cobalt poisoning include endocrine,⁶⁸ gastrointestinal,^{43,58} central^{58,139} and peripheral nervous system,¹³⁹ hematologic,^{52,83,105,166} cardiovascular,⁶⁹ and metabolic.⁶⁹ Chronic inhalational exposures affect the pulmonary system^{26,32,46,87,88,128,147} and dermatologic system.^{50,134,165} Radioactive ^{60}Co used for radiation therapy is associated with radiation burns (Chap. 134). Unlike acute toxicity, chronic cobalt exposure is not associated with an increased mortality; a cohort study evaluating more than 1100 persons with pulmonary exposures to cobalt salts and oxides over a 30-year period was unable to show an increased mortality rate.¹¹⁰

Acute Exposure

Cardiovascular. “Beer drinker’s cardiomyopathy.” In 1966, a Veterans Affairs (VA) Hospital in Nebraska cared for 28 white men with a history of beer drinking who presented with tachycardia, dyspnea, metabolic acidosis with elevated lactate concentration, and congestive heart failure.¹⁰¹ The mortality rate for these cases was 38%, and death occurred rapidly within 72 hours of presentation, due to severe acute metabolic acidosis and cardiac failure.¹⁰¹ Of the survivors, most responded immediately to supportive care and thiamine supplementation and a lack of response was found to be secondary to complications—most commonly, symptomatic pericardial effusions or embolic events.¹⁰¹ Epidemiologic evaluation of this case series revealed that these men habitually drank large quantities of beer.

Ultimately, 64 cases and 30 fatalities were reported from Nebraska.¹⁵⁴ Of the reported 30 deaths, 26 decedents received autopsies. Common postmortem findings were dilated cardiomyopathy and cellular degeneration with vacuolization and edema with a lack of inflammation or fibrosis.¹⁰¹ When cobalt was implicated in the pathogenesis of these deaths, preserved cardiac tissue of eight decedents revealed cobalt concentrations ten times greater than that of controls.¹⁵⁴

Within a year of the Nebraska cases, reports began to emerge from Quebec.¹⁰⁸ Forty-eight beer drinkers (only two of whom were women) developed unexplained cardiomyopathy with a mortality rate of 46%.¹⁰⁸ The only association between these patients was the common consumption of “brand XXX beer”.¹⁰⁸ The producers of this beer had factories in Quebec City and Montreal. The only difference between the Nebraska brewery and the one in Quebec was that the latter added ten times the amount of CoSO_4 to the beer as a foam stabilizer.¹⁰⁶ Clinical findings in these cases included tachycardia,

tachypnea, polycythemia, and low voltage electrocardiograms (ECGs).¹⁰⁷ Cases began to appear one month after beer with the higher amount of CoSO₄ was released onto the market, and no new cases were reported in Quebec after this beer with more CoSO₄ was removed from the market.¹⁰⁶

In 1972, 20 additional cases occurred in Minneapolis with similar findings of tachycardia, dyspnea, pericardial effusion, polycythemia, and metabolic acidosis with elevated lactate concentration, and there was a mortality rate of 18% acutely and 43% over a 3-year period.⁸⁰ Similar to the previous cases, all were associated with the addition of CoSO₄ as a foam stabilizer in beer.

Since the clinical findings resemble the cardiomyopathy associated with chronic alcoholism⁴⁸ and infantile malnutrition,¹²³ a debate persists as to whether cobalt is the sole cause of this syndrome. Cardiomyopathies due to poor protein intake, vitamin deficiency, and cobalt toxicity have similar histological findings. For example, myocardial biopsy of dogs with cobalt-induced cardiac failure revealed diffuse cytosolic vacuolization, loss of cross striations, and interstitial edema,¹³⁷ all of which are similar to findings of malnutrition.^{48,123} However, some other findings may be specific to cobalt-associated cardiomyopathy. For example, a small retrospective analysis revealed myocyte atrophy and myofibril loss to be present in people with cobalt-associated cardiomyopathy significantly more often than in those with idiopathic dilated cardiomyopathy.²⁴

Some animal models of cobalt cardiomyopathy were only able to reproduce pathologic and ECG findings if cobalt and ethanol⁸ were administered, while others required protein deficiency.¹³² Contrary to these studies, several murine and canine models of cobalt poisoning demonstrated cardiac lesions,^{62,136,137} cardiac failure,^{65,136,137} and ECG abnormalities while receiving nutritional supplementation.^{63,136}

Despite the implication that cobalt-induced cardiomyopathy requires malnutrition or alcoholism, a case of cardiac toxicity following acute cobalt poisoning is reported.^{68,69} However, it is difficult to identify other cases reported outside of the aforementioned small epidemics in beer drinkers. In a controlled study of occupationally exposed subjects evaluated with echocardiograms, significantly more cobalt exposed workers had diastolic dysfunction when compared to controls.⁹¹ However, none of these subjects under study developed congestive heart failure.⁹¹ Of the few reported cases of cardiomyopathy associated with arthroplastic cobaltism, patients are typically older than those with the “beer drinker’s cardiomyopathy” cohort and their nutritional status and ethanol use are unreported.^{115,121} There are rare reports of cardiomyopathy in chronically exposed workers,^{15,30,78} which suggests that the cardiomyopathy reported in the “beer drinkers” cohort is multifactorial and not solely due to cobalt.

Another source of criticism of the role of cobalt in the development of cardiomyopathy is the relatively low dose of cobalt needed to induce heart failure in these patients.⁸⁰ In patients receiving 20 to 75 mg/d of CoCl₂ for various red cell dysplasias, there were no reports of heart failure,⁸⁰ whereas the “beer drinker’s cardiomyopathy” group reportedly consumed only 6 to 8 mg/d of CoSO₄ while drinking 24 pints of cobalt-containing beer.^{80,106} All patients who developed cardiomyopathies were malnourished, which supports the theory that a multifactorial nutritional deficiency in the presence of excessive cobalt may be necessary for the development of cardiomyopathy.⁸⁰

Endocrine. Both acute and chronic cobalt exposures are associated with thyroid hyperplasia and goiter. A series of patients with severe sickle cell anemia treated with cobalt salts developed goiter with varying degrees of thyroid dysfunction.^{64,84} including clinical hypothyroidism.⁸⁵ In one patient, the goiter was so severe that airway obstruction developed.⁸⁴

Older occupational data suggest that inhalational exposure to cobalt metals, salts, and oxides may result in abnormalities in thyroid function studies.¹⁵⁵ When 82 workers in a cobalt refinery were compared to age- and sex-matched controls, exposed workers had significantly lower T₃ concentrations.¹⁵⁵ However, more recent studies of cobalt-exposed workers in environments that limit exposure do not demonstrate any changes in serum thyroid markers.⁹⁰

Within the previously mentioned beer drinker’s cardiomyopathy cohort, 11 of 14 decedents had abnormal thyroid histology.¹³³ Among them, the most common findings were follicular cell abnormalities and colloid depletion, which did not exist on thyroid analysis from 11 randomly selected autopsies that served as controls.¹³³ Of the patients with arthroprosthetic cobaltism, one patient developed clinical hypothyroidism,¹¹⁵ and another developed subclinical hypothyroidism.¹²¹

Hematologic. Anemias of the newborn,^{28,77,125} erythrocyte hypoplasia,¹⁴¹ red cell aplasia,¹⁶¹ and kidney failure associated anemia⁵⁸ have all been successfully treated with cobalt salts. Patients undergoing CoCl₂ therapy for these diseases had increased hemoglobin,^{58,125} hematocrit,^{58,125} and red cell counts.⁵⁸ Unfortunately, the effects did not persist after cessation of therapy.^{58,125}

A published series of Peruvian cobalt miners working in an open pit at 4300 meters (2.7 miles) elevation developed various clinical effects, including headache, dizziness, weakness, mental fatigue, dyspnea, insomnia, tinnitus, anorexia,

cyanosis, polycythemia, and conjunctival hyperemia consistent with acute mountain sickness.⁷⁵ When the study group was compared to age-, height-, and weight-matched high-altitude controls, the study group was noted to have higher chronic mountain sickness scores.⁷⁵ The only difference detected was elevated serum cobalt concentrations in the study group.⁷⁵

In addition to effects on red cells, recent work demonstrates transient hemolysis, methemoglobinemia, and methemoglobinuria from subcutaneous CoCl_2 exposure in mice.⁷⁰ These findings may explain reports of dark urine following cobalt exposure in other animal models.^{60,149} However, similar human cases have not been reported.

Other. Gastrointestinal distress following the ingestion of “therapeutic” doses of cobalt salts¹³⁹ and elemental cobalt are reported.⁷⁴ Decreased proprioception, impaired VIII cranial nerve function, and nonspecific peripheral nerve findings are reported with acute oral CoCl_2 exposures.¹³⁹ Patients with arthroprosthetic cobaltism are reported to have seizures, cerebellar deficits, retinopathy, hearing loss, cognitive deficits, and peripheral neuropathy; some of which had concomitant elevations of cerebrospinal fluid (CSF) cobalt concentrations.^{23,97,115,156,157}

Chronic Exposure

Pulmonary. Both asthma and “hard metal disease” are associated with cobalt exposure. Occupational asthma is reported in hard metal workers with a prevalence of 2% to 5%^{26,87,88} at exposure concentrations as low as $50 \mu\text{g}/\text{m}^3$.³⁸⁸ As is the case with most causes of occupational asthma, cobalt hypersensitivity-induced asthma is most likely immune mediated rather than toxicologic.^{29,87,147} Most hard metal workers are exposed to other metals, such as tungsten (W) and nickel (Ni), in addition to Co, and these other metals may account for some of the occupational asthma that is attributed to cobalt.^{144,146} However, in a small but well-performed study in patients with cobalt-associated asthma, intradermal cobalt chloride (CoCl_2) resulted in a positive wheal response in all subjects, and 50% of patients had a positive radioallergosorbent test (RAST) scores, which correlated to the wheal size¹⁴⁵ and suggests Co salts can illicit an immune response independent of the other metals.

Cobalt-associated pulmonary toxicity was first noted in tungsten-carbide workers^{46,66} and was subsequently referred to as “hard metal disease.” Exposures result from the process by which tungsten-carbide is sintered with cobalt. Signs and symptoms of hard metal disease may include upper respiratory tract irritation, exertional dyspnea, severe dry cough, wheezing, and interstitial lung disease ranging from alveolitis to progressive fibrosis. The prevalence of hard metal disease is largely unknown. In one study, 11 of 290 (3.8%) exposed workers were diagnosed with interstitial infiltrates on chest radiographs, but only 2 (0.7%) had a decrease in predicted total lung capacity.¹⁵⁰

Certain individuals who are exposed to large doses of hard metals for prolonged periods never develop disease, which suggests that a susceptible population exists. A glutamate substitution for lysine in position 69 of the β unit HLA-DP has a strong association with hard metal disease, similar to chronic beryllium disease.¹²⁴ Clinically, hard metal disease is difficult to distinguish from berylliosis, although an occupational history should be helpful.

Histopathologic findings of hard metal disease include multinucleated giant cells and interstitial pneumonitis with bronchiolitis.⁹ Elevated concentrations of cobalt in lung tissue can be detected,^{129,148} even as long as 4 years after exposure.¹²⁹ In patients with interstitial lung disease, bronchioalveolar lavage (BAL) commonly reveals multinucleated giant cells, type II alveolar cells, and alveolar macrophages.³² The finding of multinucleated giant cells from BAL washing is characteristic of hard metal disease.^{29,35,36,102,159}

A cross-sectional study of more than a 1000 tungsten carbide-exposed workers found an increased odds ratio of 2.1 for having a work-related wheeze when exposed to greater than $50 \mu\text{g}/\text{m}^3$ of Co.¹⁵¹ In the same study, workers with exposures recorded at greater than $100 \mu\text{g}/\text{m}^3$ had higher odds (OR 5.0) of having a chest radiograph profusion score of greater than or equal to 1/0.¹⁵¹ This profusion score, established by the United Nations agency, the International Labor Organization (ILO), is a grading system for pneumoconioses. When used to grade radiographs of asbestosis, this score correlates strongly with mortality risk,¹⁰⁰ reduced diffusing capacity, and decreased ventilatory capacity.^{67,111} A score of 0/1 is suggestive but not diagnostic (“negative”), and a score of 1/0 is presumptively diagnostic but not unequivocal (“positive”).⁵ Additional studies have similarly concluded that pulmonary disease occurs when individuals are exposed to concentrations of cobalt that approach $100 \mu\text{g}/\text{m}^3$.⁸⁶ Thus, with a margin of safety, the current threshold limit value is less than $50 \mu\text{g}/\text{m}^3$.

Until 1984, all reported cases of hard metal disease were associated with the combination of cobalt and other metals, such as nickel, cadmium and tungsten.^{9,66,88,151} When diamond polishers initiated the use of high-speed grinding disks coated with abrasive microdiamonds embedded in a matrix of cobalt powder, case reports ensued demonstrating similar clinical⁸⁹ and pathologic findings to hard metal disease, strengthening the association with cobalt.^{29,35,113} Some authors still contend that the presence of other metals^{9,66,88,151} and diamond dust^{35,59,113} are confounding factors.¹⁵⁵ Like hard metal disease, most reported cases show resolution of symptoms upon removal from the exposure,³⁵ although this is not always sufficient.¹¹³

There are very few reports of isolated cobalt exposures. In an age- and sex-matched study of 82 workers with respiratory exposures to cobalt oxides, cobalt salts, cobalt metal, and no other metal, researchers were unable to detect a difference between exposed (mean of 8 years, time weighted average = $125 \mu\text{g}/\text{m}^3$, 25% $>500 \mu\text{g}/\text{m}^3$) and unexposed workers with any objective measured pulmonary tests.¹⁵⁵ Neither group had any abnormality in chest radiography that would suggest pulmonary fibrosis.¹⁵⁵ The only significant pulmonary differences detected were a higher reported rate of dyspnea both on exertion and at rest and the presence of wheezing in the exposed group.¹⁵⁵ These authors concluded that cobalt contributes to the development of pulmonary disease but is not independently responsible for the development of pulmonary fibrosis.¹⁵⁵

Despite the progressive and debilitating nature of hard metal disease, most signs and symptoms improve with cessation of exposure.^{98,103,168} Moreover, the length and dose of exposure do not appear to correlate with the presence or severity of illness suggesting that individual susceptibility is the key determinant for developing illness.^{98,135}

Arthroprosthetic Cobaltism. It has been known for some time that metal-on-metal alloy orthopedic implants result in elevation of the associated metals in blood, urine, and hair.²⁷ Serum concentrations of cobalt become elevated 3 weeks after surgery and remain elevated through a 5-year study period, which contradicts earlier theories of elevated concentrations being related to the life of the implant.²⁰ Despite the elevation of both chromium and cobalt in measured samples, it appears that the constellation of findings is more consistent with cobalt rather than chromium.¹ However, chromium's toxicity may present in a more delayed fashion relative to cobalt.¹ Reported cases of toxicity can follow revisions, dislocations, or first-time arthroplasties of cobalt-containing prosthetics.^{97,156,157} Since these findings have been reported, the association of having a cobalt-containing prosthetic, an elevated marker of cobalt burden, and findings of end-organ toxicity has been coined "arthroprosthetic cobaltism."

Of the reported cases, some of arthroplasties have had excessive wear¹¹⁵ or have been placed following a ceramic arthroplasty resulting in metallosis.¹⁰⁰ In one case, a patient developed hypothyroidism, seizures, peripheral neuropathy, and cardiomyopathy.¹¹⁵ Unfortunately, the diagnosis was not established initially, and the hip revision resulted in improvement of serum cobalt concentrations and thyroid markers but the patient had permanent neurologic sequelae.¹¹⁵ Furthermore, one patient with cobaltism with evidence of cardiac tamponade, hypothyroidism, hearing loss, and polycythemia underwent implant removal and chelation with 2,3-dimercaptopropane-1-sulfonate, which resulted in decreased blood cobalt concentrations but permanent hearing loss.¹²¹ However, other case reports of metallosis from cobalt arthroplasties suggest clinical manifestations of cobaltism improve following revision.^{156,157} It appears that lumbar metal-on-metal total disk replacements are associated with smaller elevations in serum cobalt concentrations when compared to hip resurfacing or total hip arthroplasties,¹⁹ but there are no reported cases of clinical cobaltism with lumbar implants. Finally, within this cohort, retinal effects have been noted in at least two case reports.^{10,11} The pathophysiology of these cases is poorly understood and confounded by comorbidities typical in this cohort of patients.

Renal. A single report associates reversible acute kidney injury with the chronic administration of CoCl_2 as treatment for anemia.¹³⁹ Some animal models of cobalt cardiomyopathy demonstrate cellular changes in renal tissue.⁶¹ However, when 26 exposed hard metal workers were evaluated for urinary albumin, retinol binding protein, β_2 -microglobulin, and tubular brush border antigens no detectable differences could be found between the study group and controls.⁵⁴ Additionally, patients with cobalt-containing total hip arthroplasties were followed over 2 years with elevated serum cobalt concentrations without any significant effect on serum creatinine over this study period.¹⁴ Based on these few reports, it appears that acute and chronic exposure to cobalt has little effect on the kidneys.

Dermatology. In a study of 1782 construction workers, 23.6% developed dermatitis and 11.2% developed oil acne while using cobalt-containing cement, fly ash, or asbestos.⁸¹ As in hard metal disease, it is difficult to isolate cobalt as the sole contributor to the development of dermatitis. Nickel (Chap. 99) is the classic toxicant causing dermatitis. Commonly found in some of these construction occupations, it may be implicated in the development of cutaneous manifestations.^{50,134} However, consumer products such as piercings, tattoo ink, plastics, clothing dye, makeup, and dental treatments are implicated in cobalt-induced allergic contact dermatitis.⁵³ Furthermore, in vitro studies demonstrate that cobalt can induce production of both Th1- and Th2-type cytokines in peripheral blood mononuclear cells—the same pathway implicated in nickel contact dermatitis.¹⁰⁴ Thus, it appears that cobalt can independently induce a hypersensitivity reaction independent of the presence of nickel.

Reproduction. In pregnant rats, CoCl_2 exposure neither results in teratogenicity nor fetal toxicity.¹¹⁹ In a case report of a pregnant woman with hard metal disease, the woman was able to bring the pregnancy to term and deliver without complication.¹²⁷ In another case report, a woman with a cobalt-containing hip arthroplasty had repeated joint aspirations, dislocations, and revisions before and during her pregnancy.⁵⁶ Cobalt concentrations of this mother were 138 to $143 \mu\text{g}/\text{L}$ throughout the pregnancy, cord blood concentration was $75 \mu\text{g}/\text{L}$, and infant blood concentration at 8 weeks was $13 \mu\text{g}/\text{L}$. Despite these elevated concentrations, there was no clinical evidence of toxicity.⁵⁶ It is hypothesized that only exposures

toxic to the mother result in fetal toxicity.⁴²

In mice, chronic exposure to cobalt results in impaired spermatogenesis and decreased fertility without affecting follicular stimulating hormone or leuteinizing hormone, whereas acute exposures did not demonstrate similar reproductive effects.¹²⁰ Additional murine studies discuss the possible interactions between cobalt with iron and zinc, which are both essential elements for spermatogenesis.⁶ Despite these findings, there are no reported human cases that associate cobalt exposure with teratogenicity or impaired fertility.

Carcinogenesis. Animal experiments with injection of CoCl_2 into soft tissue resulted in soft tissue sarcomas, leading the International Agency for Research on Cancer (IARC) to consider cobalt metal without tungsten carbide and cobalt sulfate and other soluble cobalt (II) salts possibly carcinogenic to humans (group 2B).^{18,33,44,152,167} It was suggested that cobalt metal associated with tungsten carbide was probably carcinogenic to humans (group 2A).¹⁶⁷ There are case reports and cohort studies that suggest that pulmonary exposure to Co^{2+} increases the risk of lung cancer. However, these studies were unable to control for other known carcinogens such as arsenic.³³ In the largest cohort study to date, which followed more than 1100 workers for more than 38 years, there was no increase in the prevalence of lung cancer.¹⁰⁹

DIAGNOSTIC TESTING

Body fluid cobalt concentrations are not readily available and therefore cannot be used to direct emergent clinical care. Some adjunctive testing that may support a clinical diagnosis of cobalt toxicity should include a complete blood count (CBC), reticulocyte count, erythropoietin (EPO) concentration, and thyroid-stimulating hormone (TSH) concentration. The results of these tests may reflect the level of exposure or potential toxic manifestations.

Cardiac Studies

ECG, echocardiogram, and radionuclide angiocardigraphy with ⁹⁹Tc(RNA) are useful screening tests for detecting abnormalities associated with cobalt cardiomyopathy and/or pulmonary hypertension due to hard metal disease.³⁰ It is important to remember that these cardiac tests are neither specific nor diagnostic of cobalt-induced cardiomyopathy.

Pulmonary Testing

Patients with hard metal lung disease may demonstrate bilateral upper lobe interstitial lung disease on chest radiograph. However, patients may have signs and symptoms of disease without specific radiographic findings.¹²⁷ Pulmonary function testing in occupationally exposed workers may show decreased vital capacity¹²⁷ and a decrease in transfer factor for carbon monoxide, both of which may be useful in identifying patients at risk for developing pulmonary fibrosis.¹⁵⁴ Some authors suggest an inversion of CD4/CD8 ratio in BAL washings as a useful tool for diagnosis and evaluation of progression of illness and that normalization is a marker for improvement.¹²⁸ Despite these available tests, a definitive diagnosis of hard metal disease requires a tissue sample with findings of multinucleated giant cells in the setting of interstitial pulmonary fibrosis.

Cobalt Testing

Cobalt, as stated above, is primarily eliminated in the urine and to a lesser extent in the feces making urine cobalt evaluation most appropriate.⁹³ The difficulty lies in the interpretation of the result. Cobalt is detectable in the urine after inhalational exposure and reflects elimination kinetics that are rapid during an initial exposure but slow after prolonged exposure.^{93,138} Due to this variable elimination pattern, it is difficult to interpret both urine and blood concentrations unless the dose and length of exposure are precisely known. Furthermore, the defined patterns may be applicable only to shift workers utilizing soluble forms of cobalt.⁹³

Further complicating the interpretation of urinary cobalt concentrations is the abundance of organic cobalt in the form of vitamin B₁₂. A detailed vitamin supplementation history is required prior to the interpretation of a urine or blood cobalt concentration, as a diet regimen high in vitamin B₁₂ may increase urine cobalt concentrations. For this reason, speciation of cobalt has been investigated. The ratio of inorganic to organic cobalt is higher in occupationally exposed workers (2.3) when compared to controls (1.01), independent of the wide variations of urinary cobalt concentrations.⁵⁷ This is a promising area of study for the evaluation of cobalt exposed workers.

Toxic concentrations of cobalt in serum and urine are poorly defined. Published literature on “normal values” is fraught with variability, which may reflect differences in the population under study techniques for measurement. Normal serum concentrations of cobalt are frequently reported as 0.1 to 1.2 $\mu\text{g/L}$.^{3,16,68,69,72,143} In comparison, a single acutely poisoned patient had a reported serum concentration of 41 $\mu\text{g/L}$.⁶⁸ In the “arthroprosthetic cobaltism” group, serum cobalt concentrations ranged from 24 to 625 $\mu\text{g/L}$.^{56,98,116,122,157} In contrast, several case series of metal-on-metal hip arthroplasties and resurfacings demonstrate peak serum cobalt concentration not to exceed that of 11.5 $\mu\text{g/L}$ barring one outlier of 35 $\mu\text{g/L}$ at 1 year postprocedure.^{14,19,20} Based on this data, some recommend that the risk of “arthroprosthetic

cobaltism” be suspected when serum cobalt concentrations exceed 10 µg/L.¹⁵⁷

Normal reference urine cobalt concentrations are between 0.1 and 2.2 µg/L.^{3,16,68,69,72,118,143} In contrast, an acute elemental cobalt ingestion resulted in a concentration of 1700 µg/L on a spot urinalysis several days after the exposure.⁶⁹ In the “arthroprosthetic cobaltism” cases, one patient had a urine cobalt concentration of 16,500 µg/L.¹¹⁵

Chronic exposures should be evaluated differently as discussed above (see Toxicokinetics). Exposed workers, without clinical disease, have reported spot urine concentrations that range from 10 µg/L to several hundred µg/L.⁷¹

TREATMENT

Acute Management

Patients with acute cobalt poisoning require aggressive therapy. It is reasonable to conclude that the same decontamination principles used for other metals apply to cobalt. There have been no studies examining the benefit of gastric emptying, activated charcoal, or whole bowel irrigation. An attempt of whole-bowel irrigation for radiopaque solid forms of cobalt should be made prior to endoscopic or surgical removal. Regardless of the decontamination procedure utilized, chelation therapy should not be initiated until the gastrointestinal cobalt source has been removed. If there is a large stomach burden in solid form, endoscopic or surgical removal may be of benefit,⁶⁹ keeping in mind that the administration of activated charcoal prior to surgical removal may obscure visualization of the surgical field (Chap. 8). After decontamination, reduction of tissue burden and prevention of end-organ toxicity is the next crucial step.

The data on chelation therapy is unfortunately limited to animal models^{37–42,94–96} and human case reports.^{69,121} The basis of chelation therapy originates from the mid 1900s when oral protein intake was found to result in a reduction of cobalt toxicity in calves⁴⁵ and rats.⁶² Certain sulfur containing proteins serve as good chelators for some transition metals.

In a series of animal models of acute cobalt toxicity, several agents N-acetylcysteine (NAC), succimer, ethylenediaminetetraacetic acid (EDTA), glutathione, and diethylenetriaminopentaacetic acid (DTPA) were evaluated for their ability to enhance urinary and fecal elimination of cobalt.⁹⁶ Succimer and EDTA were able to enhance fecal elimination.⁹⁶ Glutathione and DTPA were able to enhance urinary elimination, and NAC was able to enhance elimination by both routes.⁹⁶

In two separate animal studies, NAC reduced tissue burden and injury due to cobalt in the liver and spleen.^{41,96} Glutathione, another sulfur-containing protein, also reduced tissue concentrations of cobalt but only in the spleen.⁹⁶

The sulfur-containing proteins, NAC,^{38,41} L-cysteine,^{37,38} L-methionine,³⁸ and L-histidine,⁴² were studied for their ability to reduce mortality in rats that were administered an LD₅₀ of CoCl₂ orally and intraperitoneally. Therapies with NAC, L-cysteine, and L-histidine⁴² are more effective than L-methionine in protecting against mortality, upward of 100% protection. In a similar fashion, Na₂EDTA effectively reduced mortality.⁴⁰ In all these therapies, the successful reduction in mortality from these therapies is predicated on its early administration.^{37,38,40–42}

In a murine model, L-cysteine, NAC, glutathione, L-histidine, sodium salicylate, D,L-penicillamine, succimer, N-acetylpenicillamine (NAPA), diethyldithiocarbamate (DDC), BAL, 4,5-dihydroxy-1,3-benzene disulfonic acid, Na₃CaDTPA, Na₂CaEDTA, and deferoxamine mesylate were each evaluated for exposures to an LD₅₀ and an LD₉₉ of CoCl₂.⁹⁵ Sodium salicylate, NAPA, DDC, BAL, 4,5-dihydroxy-1,3-benzene disulfonic acid, and deferoxamine mesylate were all ineffective at improving survival following an LD₅₀.⁹⁵ Chelators that were seemingly effective at an LD₅₀ and not at an LD₉₉ were L-histidine and D,L penicillamine.⁹⁴ NAC, L-cysteine, and succimer were able to improve survival by 40% to 50%.⁹⁵ The most effective chelators at LD₉₉ were EDTA and DTPA.^{94,95} An expanded analysis of these data revealed that EDTA and DTPA had a better therapeutic index when compared to succimer.⁹⁵ In this study, BAL was ineffective as is suggested in an in vitro study where BAL was unable to chelate Co²⁺ that is already bound to α-ketoglutarate.¹⁶³

Human chelation data are available from two case reports.^{69,121} In the first, a child ingested multiple elemental cobalt containing magnets yielding a serum cobalt concentration of 41 µg/L.⁶⁹ Five days of 50 mg/kg/d of intravenous CaNa₂EDTA enhanced renal elimination of cobalt, and the patient’s metabolic acidosis and the cardiac dysfunction also resolved simultaneously.⁶⁹ In the second, a 56 year-old man developed “arthroprosthetic cobaltism” with elevated serum (506 µg/L) and CSF concentrations (8.5 µg/L) of cobalt and evidence of hypothyroidism, cardiomyopathy with pericardial effusion, polycythemia, and both central and peripheral neuropathy.¹²¹ Unlike the previous case report, this patient was treated 2,3-dimercaptopropane-1-sulfonate (DMPS) at a dose of 14 mg/kg for 6 days and followed by 4 mg/kg for 5 days for a total of 10 g of antidote. The authors were able to demonstrate a 26% reduction in serum cobalt concentrations 1 month following treatment.¹²¹ However, despite removal of the prosthesis and chelation therapy, the patient had permanent

hearing loss and a persistently elevated serum concentration.¹²¹ This permanent hearing loss and persistently elevated serum concentration are most likely due to a delay of 7 months from onset of symptoms and metallosis of tissue to treatments.

In conclusion, based on a single human case report, several animal studies and safety profiles, CaNa_2EDTA and NAC can be used as antidotal therapy. Indications for treatment should include patients who demonstrate end-organ manifestations of toxicity. This includes metabolic acidosis and cardiac failure. Other manifestations of severe cobalt toxicity such as pericardial effusion, clinically significant goiter, and hyperviscosity syndrome should be treated aggressively with pericardiocentesis, airway protection, and phlebotomy, respectively. Based on years of experience with lead, CaNa_2EDTA should be administered as doses of 1000 mg/m²/d by continuous infusion for 5 days. If the diagnosis is confirmed and signs of cardiac failure and metabolic acidosis persist after 5 days, an alternate chelator (succimer or DTPA) can be started. Similarly, NAC dosing should be based on the acetaminophen (APAP) experience. The 20 hour intravenous NAC protocol should be initiated and continued as in the case of fulminant hepatic failure (Antidotes in Depth: A3) for as long as the patient can tolerate therapy or continued if cardiac failure or acidemia persists. If there are contraindications to intravenous NAC, oral NAC can be administered using one of the APAP treatment regimens. Thiamine hydrochloride should be administered to all patients presenting with or without overt cardiomyopathy independent of whether the patient is alcoholic or malnourished. The dose of thiamine is not well defined but should be based on its safety and clinical experience with the treatment of Wernicke encephalopathy. The daily administration of 100 mg of parenteral thiamine can be initiated with increasing doses to 100 mg every hour for life threatening manifestations (cardiac failure and metabolic acidosis) (Antidotes in Depth: A24).

Arthroplasty Cobaltism

It appears that clinical symptoms and serum cobalt reduction respond well to arthroplasty revision^{115,121,156} and potentially chelation therapy.¹²¹ The key to treatment of this entity is early clinical suspicion with the constellation of findings of cardiomyopathy, hypothyroidism, polycythemia, and peripheral and central nervous system impairment. Early arthroplastic revision supports the decontamination tenets within this text and published in case reports,^{115,121,156} however, emergent revisions may not be practical in an acutely ill patient. Therefore, the only modality of treatment other than supportive may be chelation. However, based on limited literature, it is unclear if chelation in the presence of a large reservoir of metal can mobilize cobalt. However, the single case report of DMPS treatment for a patient with “arthroprosthetic cobaltism” (including cardiomyopathy, neurologic derangements, hypothyroidism, and polycythemia) was able to demonstrate a decrease in serum cobalt concentration and an increase in urinary cobalt concentration postchelation.¹²¹

Occupational/Chronic Exposure

As is always the case of occupational poisonings, prevention is of paramount importance. The utilization of skin and respiratory protection and improvement of personal hygiene has reduced exposure and subsequently the amount of urinary cobalt in occupationally exposed workers.⁹² Barrier and emollient creams cannot prevent the dermatitis associated with cobalt metal exposures.⁵¹

Large statistically significant reductions in urinary cobalt concentrations were demonstrated after the implementation of aspirator systems over machines in the production of Widia-steel.²⁵ These aspirators were found to reduce ambient cobalt concentrations by as much as a factor of six.⁴⁷

SUMMARY

- Acute cobalt toxicity results in multiorgan system toxicity, including the cardiac, endocrine, hematopoietic, gastrointestinal, and neurologic systems.
- Arthroprosthetic cobaltism is unique in that there is a large reservoir of metal, and the clinical presentation may be subacute and mistaken for other disease processes.
- The evaluation and treatment of all patients will be determined by the cobalt source and type (elemental, inorganic, or organic), route of poisoning, and time and duration of exposure.
- Treatment of patients with chronic occupational exposures to cobalt is mainly symptomatic and is often dependent on improved industrial hygiene and removal from the source.
- Acute poisoning with end organ manifestations may require aggressive gastrointestinal decontamination and chelation therapy utilizing CaNa_2EDTA and NAC, and at times, succimer.

95 COPPER

Lewis S. Nelson

Copper (Cu)

Atomic number = 29

Atomic weight = 63.5 Da

Normal concentrations

Whole blood = 70–140 µg/dL (11–22 µmol/L)

Total serum = 120–145 µg/dL (18.8–22.8 µmol/L)

Free serum = 4–7 µg/dL (0.63–1.1 µmol/L)

Ceruloplasmin = 25–50 µg/dL (3.9–7.8 µmol/L)

Urine = 5–25 µg/24 h (0.078–3.9 nmol/L)

HISTORY AND EPIDEMIOLOGY

Copper exists naturally, either as native copper (elemental copper, Cu⁰) or as one of its sulfide or oxide ores. Important ores include malachite (CuCO₃·(OH)₂), chalcocite (Cu₂S), cuprite (Cu₂O), and chalcopyrite (CuFeS₂ or Cu₂S·Fe₂S₃).

Chalcopyrite, a yellow sulfide ore, is the source of 80% of the world's copper production. The smelting, or separation, of copper ores began about 7000 years ago; copper gradually assumed its current level of importance at the start of the Bronze Age, around 3000 BC. Smelting begins with roasting to dry the ore concentrate, which, in more modern times, is further purified by electrolysis to a 99.5% level of purity. The sulfide ores have a naturally high arsenic content, which is released during the extraction process, posing a risk to smelters.

Although acute copper poisoning is uncommon in the United States, the historical therapeutic role of copper remains noteworthy. Copper sulfate was used in burn wound débridement until cases of systemic copper poisoning were reported.⁵¹ Interestingly, in one report, each wound débridement procedure was associated with an 8% to 10% fall in the patient's hematocrit. In the 1960s, copper sulfate (250-mg dose, containing 100 mg copper ion) ironically was recommended as an emetic agent, typically for use in children following potentially toxic exposures.⁶⁰ It was recognized for its rapidity of onset and effectiveness, and it compared favorably with syrup of ipecac. However, copper-induced emesis was rapidly identified as a highly dangerous practice, and this use was generally discontinued,^{68,111} although fatal cases still occur. Copper salts are administered in religious rituals as a green-colored “spiritual water,” containing 100 to 150 g/L of copper sulfate as an emetic to “expel one's sins.”^{5,110}

There is a growing body of knowledge linking copper to the promotion of both physiologic and malignant angiogenesis.⁴⁷ In this latter case, copper may enable tumor expansion, invasion, and metastasis. Additionally, copper binding to amyloid fibers in the brains of patients with Alzheimer disease may lead to local oxidative damage and cause the characteristic neurodegeneration.¹⁹ Copper is also similarly implicated in the pathogenesis of both Parkinson disease and autism.^{22,126}

Acute or chronic copper poisoning can occur when the metal is leached from copper pipes or copper containers. This occurs frequently when carbon dioxide gas, used for postmix soft drink carbonation, backflows into the tubing transporting water to the soda dispensers, creating an acidic solution of carbonic acid that leaches copper from the equipment pipes.¹²² Similarly, storage of acidic potable substances, such as orange or lemon juice, in copper vessels may cause copper poisoning. A particularly dangerous situation occurs when acidic water is inadvertently used for hemodialysis.^{35,74} In this circumstance, the leached copper avoids the normal gastrointestinal barrier and is delivered parenterally to the patient's circulation. In one reported series, the copper concentration in the dialysis water was 650 µg/L, causing several poisonings and the death of a patient with a whole-blood copper concentration of 2095 µg/L.³⁶ Similarly, stagnant water or hot water,¹⁰⁰ even if not highly acidic,¹⁰⁴ can accumulate copper ions from pipes and cause poisoning.^{7,36}

Although most natural water contains a small quantity of copper (4–10 µg/L), it is tightly bound to organic matter and therefore not orally bioavailable. Copper pipes typically add about 1 mg of copper to the daily intake of an adult. The

Environmental Protection Agency guidelines permit up to 1.3 mg/L of copper in drinking water,²⁹ although in some areas intermittent concentrations may rise as high as 60 mg/L.

Metallic copper is ideal for electrical wiring because it is highly malleable and can be drawn into fine wire. Its electrical conductivity is only exceeded by silver. Similarly, its excellent heat conductivity accounts for its widespread use in cookware. Although the metal is reactive with air, it forms a resistant layer of insoluble copper carbonate on its surface. It is this water-and air-resistant compound that accounts for the green coloration of ornamental roofing and statues. Because copper is a soft metal, it must be strengthened prior to use in structural applications or as a coinage metal. This is most commonly done by the creation of copper alloys. Brass is an alloy of copper compounded with as much as 35% zinc. Similarly, bronze contains copper combined with up to 14% tin. Gun metal is an alloy that contains 88% copper, 10% tin, and 2% zinc. Sterling silver and white gold also contain copper.

CHEMICAL PRINCIPLES

Metallic copper (Cu^0), although not in itself poisonous, may react in acidic environments to release copper ions. The metallic copper contraceptive intrauterine device derives its efficacy from the local release of copper ions.¹⁴ Metallic copper bracelets, worn by patients with rheumatoid arthritis and other ailments, purportedly derive their far-reaching antiinflammatory effect through dermal copper ion absorption and distribution to affected tissues.¹¹⁹ Local copper ion release is responsible for the occasional case of dermatitis that occurs following skin exposure to copper metal.⁵² Ingestion of large amounts of metallic copper (eg, as coins) may rarely produce acute copper poisoning.^{95,125} Poisoning under these circumstances is a result of the release of large amounts of copper ion from copper alloy by the acidic gastric contents. Also, inhalation of finely divided metallic copper dust or bronze powder, used in industry and for gilding, may produce life-threatening bronchopulmonary irritation, presumably as a consequence of the local release of ions.^{34,45}

The majority of patients suffering from acute copper poisoning are exposed to ionic copper. In copper sulfate, also known as cupric sulfate, the copper atom is in the +2 oxidation state. Copper sulfate is used as a fungicide and algicide, and to eradicate tree roots that invade septic, sewage, and drinking water systems.⁹³ Copper sulfate is the most readily available form and is the form involved in the majority of nonindustrial copper salt exposures. Copper sulfate was a favorite ingredient in many home chemistry sets because of its brilliant blue color when dissolved in water. Although serious poisoning, particularly in children, led regulatory agencies in the United States to restrict its use, it accounts for the most consequential chemistry set-related toxic exposures reported in other countries.⁷⁹ Similarly, homegrown copper sulfate crystals from kits are occasionally responsible for fatal poisonings.⁴³

Cuprous salts, containing copper in the +1 oxidation state, are unstable in water and readily oxidize to the cupric form. There are numerous copper salts with varying oxidation states used in industry and agriculture (Table 95–1), many of which are not poisonous. Because those salts that are water soluble are more likely to be toxic, it is important to determine the nature of the copper product implicated in an exposure. Analogously, when examining the medical literature, it is critical to discern which form of copper is involved in the scientific experiment or case report before applying the results to clinical practice.

TABLE 95–1. Important Copper Products

Chemical Name	Chemical Structure	Common Name	Notes
Chalcopyrite	CuFeS_2	Copper iron sulfide	Copper ore; source of 80% of world's copper
Chromated cupric arsenate	35% CuO 20% CrO_3 45% As_2O_3	CCA	Wood preservative ^a
Copper octanoate	$\text{Cu}[(\text{CH}_3(\text{CH}_2)_6\text{COO})_2]$	Copper soap	Fungicide in home garden products, paint, rot-proof rope, and roofing
Copper triethanolamine complex	$\text{Cu}[(\text{HOCH}_2\text{CH}_2)_3\text{N}]_2$	Chelated copper	Algicide
Cupric acetoarsenite	$\text{Cu}(\text{C}_2\text{H}_3\text{O}_2)_3 \cdot 3\text{Cu}(\text{AsO}_2)_2$	Paris or Vienna green	Insecticide, wood preservative, pigment ^a
Cupric arsenite	CuHAsO_3	Swedish or Scheele's green	Wood preservative, insecticide ^a
Cupric hydroxide	$\text{Cu}(\text{OH})_2$	Copper hydroxide	Fungicide
Cupric chloride	CuCl_2		Catalyst in petrochemical industry
Cupric chloride, basic	$\text{CuCl}_2 \cdot 3\text{Cu}(\text{OH})_2$	Basic copper chloride; copper oxychloride	Fungicide
Cupric oxide	CuO	Black copper oxide; tenorite	Glass pigment, flux, polishing agent
Cupric sulfate	CuSO_4	Roman vitriol, blue vitriol, bluestone, hydrocyanite	Fungicide, plant growth regulator, white-wash, homegrown crystals
Cupric sulfate, basic	$\text{CuSO}_4 \cdot 3\text{Cu}(\text{OH})_2 \cdot 3\text{CaSO}_4$	Bordeaux solution	Fungicide
Cuprous cyanide	CuCN	Cupridin	Electroplating solutions
Cuprous oxide	Cu_2O	Red copper oxide, cuprite	Antifouling paint

^aNo longer used in the United States.

PHARMACOLOGY AND PHYSIOLOGY

Copper is an essential metal that our body stores in milligram amounts (100–150 mg). Daily requirements of copper are approximately 50 µg/kg in infants and 30 µg/kg in adults. The average daily intake of copper in the United States noted in NHANES III is about 1.2 mg.³⁷

The daily requirement is satisfied by nuts, fish, and green vegetables such as legumes, although our largest source is generally from drinking water. Copper deficiency is exceedingly rare even in the poorest communities and is most frequently acquired through the excessive zinc intake.⁸³ There are genetic aberrations, such as Menkes “kinky-hair” syndrome, in which intestinal copper uptake is impaired. Menkes syndrome is characterized by mental retardation, thermoregulatory dysfunction, hypopigmentation, connective tissue abnormalities, and pili torti (kinky hair). Interestingly, with the increased focus on the role of copper in neurodegenerative disorders and cancer, some authors suggest intentionally depleting patients of their copper stores with tetrathiomolybdate, an experimental copper chelator.⁴⁰

Copper is absorbed by an active process involving a copper adenosine triphosphatase (CuATPase, also known as the Menkes ATPase) in the small intestinal mucosal cell membrane (see below). The gastrointestinal absorption varies with the copper intake and the food source,⁴⁸ and is as low as 12% in patients with high copper intake. In the presence of damaged mucosa, such as following acute overdose, the fractional absorption is likely to be significantly higher.⁶⁹ Once absorbed, copper is rapidly bound to high-affinity carriers, such as ceruloplasmin, and low-affinity carriers, such as albumin, for transport to the liver and other tissues.¹²⁰ Under normal circumstances the amount of unbound copper in the blood is well below 1%. After being released locally in the reduced form from its carrier, copper uptake by the hepatic cells occurs via a specific uptake pump.⁹⁷ This process, which is facilitated by the reducing agent ascorbic acid, provides a potential window, however brief, for detoxification of the ion by chelating agents. In acute overdose, a high fraction of the plasma copper remains bound to low-affinity proteins, such as albumin, and thus is biologically active.

In the hepatocyte, complex trafficking systems exist (involving ceruloplasmin, metallothionein, and other metallochaperones within the cytoplasm) to prevent copper toxicity and to aid delivery to the appropriate enzymes.⁹⁴ A distinct Cu-ATPase, located on certain subcellular organelles such as the trans-Golgi network or pericanalicular lysosomes, assists in the appropriate localization and elimination, respectively, of the metal.¹²¹ By this mechanism, copper

is either incorporated into enzymes or released, as a metallothionein–copper complex, directly into the biliary system for fecal elimination.

Some copper released from the liver is bound primarily to ceruloplasmin, an α_2 -sialoglycoprotein with a molecular weight of 132,000 Da. Ceruloplasmin-bound copper accounts for approximately 90% to 95% of serum copper. Ceruloplasmin is a multifunctional protein that binds 6 atoms of copper per molecule. Copper bound to this carrier has a plasma half-life of approximately 24 hours. Ceruloplasmin is also involved in the mobilization of iron from its storage sites, and it serves an analogous role as a ferroxidase during the ferrous–ferric conversion. Cu^+ is oxidized directly by ceruloplasmin, thereby avoiding the generation of reactive oxygen species.

There are several important copper-containing enzymes in humans (Table 95–2). The common link among these enzymes is their participation in reduction-oxidation (redox) reactions in which a molecule, typically oxygen, donates or shares its electrons with another compound. In this respect, the physiology, chemistry, and toxicology of copper are most similar to that of iron. In fact, “blue-blooded” animals, such as octopi and spiders, use copper in hemocyanin, a blue pigment, in an analogous manner that “red-blooded” animals use iron in hemoglobin.

TABLE 95–2. Important Copper-Containing Enzymes and Proteins and Their Functions

<i>Enzyme or Protein</i>	<i>Function</i>
Alcohol dehydrogenase	Metabolism of alcohols
Catalase	Detoxifies peroxide
Ceruloplasmin enzymes	Copper transport, ferroxidase
Cytochrome C oxidase	Electron transport chain
Dopamine β -hydroxylase	Converts dopamine to norepinephrine
Factor V	Coagulation cascade
Lysyl oxidase	Cross links collagen and elastin
Monoamine oxidase	Deamination of primary amines
Superoxide dismutase	Detoxifies free radicals
Tyrosinase	Melanin production

The volume of distribution of copper is 2 L/kg and the $t_{1/2}$ of erythrocyte copper is 26 days. The elimination of copper occurs predominantly through biliary excretion following complexation with ceruloplasmin. Biliary excretion approximates gastrointestinal absorption and averages 2000 $\mu\text{g}/24\text{ h}$.⁹⁴ Renal elimination under normal conditions is trivial, accounting for approximately 5 to 25 $\mu\text{g}/24\text{ h}$.

Copper in water may be tasted at concentrations of 1 to 5 mg/L, and a blue-green discoloration is imparted when the concentrations are greater than 5 mg/L.³³ Acute gastrointestinal effects occurs when drinking water contains more than 25 mg/L,⁵³ although concentrations as low as 3 mg/L are associated with abdominal pain and vomiting in many, without a rise in the serum copper concentrations.⁹² In one blinded, randomized study comparing copper-adulterated water to pure water, women appeared more sensitive than men to copper, but both groups were symptomatic when the copper concentration in the water was 6 mg/L.⁶

TOXICOLOGY AND PATHOPHYSIOLOGY

Redox Chemistry

Because copper is a transition metal, it is capable of assuming one of several different oxidation (or valence) states, and it is an active participant in redox reactions. In particular, participation in the Fenton reaction and Haber-Weiss cycle explains the toxicologic effects of copper as a generator of oxidative stress and inhibitor of several key metabolic enzymes (Fig. 12–2).⁵⁷ In the presence of sulfhydryl-rich cell membranes, such as those on erythrocytes, cupric ions are reduced to cuprous ions, which are capable of generating superoxide radicals in the presence of oxygen.⁶⁴ This one-electron reduction of oxygen regenerates the cupric ion, allowing redox cycling and continuous generation of reactive oxygen species (Fig. 95–1). In particular, the mitochondrial electron transport chain and lipid membranes serve as ready sources of electrons for copper reduction, establishing a chain of events that ultimately leads to mitochondrial or membrane dysfunction,

respectively.⁸²

FIGURE 95–1. In the cupric or Cu²⁺ state, copper is reduced by sulfhydryl-containing compounds such as glutathione (GSH) or dimercaptopropane sulfonate (DMPS) to its cuprous form (Cu⁺), forming disulfide links in the process. Oxidized glutathione (GSSG) is subsequently enzymatically reduced by glutathione reductase to regenerate GSH. Superoxide anions (O₂⁻), formed when molecular oxygen (O₂) acquires an additional electron, are continually generated by mitochondria. Both the Fenton and the Haber-Weiss reactions use the cuprous form of copper as a catalyst to convert hydrogen peroxide or superoxide radical into the more biologically consequential hydroxyl radical (OH[•]).

Erythrocytes

Cupric ion inhibits sulfhydryl groups on enzymes in important antioxidant systems, including glucose-6-phosphate dehydrogenase and glutathione reductase.¹⁰¹ However, while support for these effects is only indirect, intraerythrocyte concentrations of reduced glutathione fall demonstrably following copper exposure. This effect is presumably part of the protective role that glutathione, a nucleophile or reducing agent, normally has on oxidants, such as either cupric ions or the reactive oxygen species they generate.^{76,77} Thus, in the setting of copper poisoning, in which excessive quantities of oxidants are produced, the depletion of glutathione presumably augments peroxidative membrane damage.

The importance of hemoglobin-derived reactive oxygen species is demonstrated by the lack of hemolysis in the presence of copper under anaerobic conditions or in an environment saturated with carbon monoxide.¹¹ The in vitro hemolytic activity of copper sulfate is reduced by albumin and several sulfhydryl containing compounds, including D-penicillamine and succimer.¹ Interestingly, dimercaptopropane sulfonate (DMPS), another sulfhydryl containing compound often used as a chelator, exacerbates copper-induced hemolysis. This paradoxical effect is variably attributed to concomitant inhibition of superoxide dismutase, an important antioxidant enzyme, or to the ability of DMPS to efficiently reduce either membrane dithiols or cupric ions, in either case increasing the generation of superoxide.²

Hemolysis frequently occurs within the first 24 hours following with acute copper poisoning.^{26,110,124} This rapidity of hemolysis differs markedly from most other oxidant stressors, which may take several days, and is likely a result of the differing nature of the erythrocyte insult. That is, the hemolysis following most oxidant exposures is caused by precipitation of hemoglobin as Heinz bodies and subsequent erythrocyte destruction by the reticuloendothelial system. Hemoglobin precipitation may also occur in the setting of acute copper poisoning, particularly following less substantial exposure. Additionally, and accounting for the early hemolysis, copper also directly oxidizes the erythrocyte membrane, thereby initiating red cell lysis independently of the reticuloendothelial system.⁹⁹ Oxidant-induced disulfide cross-links in the erythrocyte membrane reduce its stability and flexibility, thereby predisposing to early cell rupture.³

Copper-induced oxidation of the heme iron within the erythrocyte produces methemoglobinemia.⁸⁰ Given the high incidence of hemolysis, the methemoglobin is commonly released within the plasma. In this situation, methylene blue may not reliably reduce the ferric iron.

Liver

Although most of the accumulated copper in hepatocytes is rapidly complexed with metallothionein or otherwise used, unsequestered copper ions participate in redox reactions. Hepatic cells are protected from copper toxicity in vitro by induction of metallothionein with zinc or cadmium salts or by the infusion of metallothionein prior to exposure. These interventions demonstrate the toxicologic significance of free intracellular copper. These findings also explain the therapeutic use of zinc acetate in patients suffering from Wilson disease, because copper itself is not a good inducer of

metallothionein in humans.

Copper ions also generate hydroxyl radicals, which are potent inducers of both lipid peroxidation, and other reactive oxygen species. The peroxidative effect on biologic membranes is more significant in animals deficient in vitamin E and is prevented by vitamin E replacement, presumably because of the role of vitamin E as a free radical scavenger.¹⁰⁸ These effects are most pronounced in mitochondria, perhaps as a consequence of the reduction of cupric to cuprous ion in these organelles.^{42,109} Copper also accumulates in the cellular nuclei, where localized production of hydroxyl radicals may form DNA adducts and cause apoptosis.⁹⁸ Histologically, liver damage follows a centrilobular pattern of necrosis ([Chap. 23](#)).

The sequelae of the potent hepatotoxic effects of copper are not isolated to the liver. Once liver necrosis occurs, typically at liver copper concentrations greater than 50 mg/g dry weight, massive release of copper into the blood occurs, which may be of sufficient magnitude to cause hemolysis. This sequence of events is common during the crises of Wilson disease and may allow for an understanding of the delayed secondary episode of hemolysis that occurs in some copper-poisoned patients.

Kidney

The kidneys bioaccumulate copper, where it is bound primarily to metallothionein. Reactive oxygen species are probably also responsible for the nephrotoxic effects of unbound copper. Pathologic analyses of the kidneys of oliguric or anuric patients typically reveal acute tubular necrosis that may demonstrate hemoglobin casts. These findings suggest that kidney failure may result indirectly from the hemoglobinuria induced by the massive release of free extracellular hemoglobin. The urinary hemoglobin, like myoglobin, may undergo conversion to ferriheme or release its iron, either of which results in oxidative stress on the renal tubular epithelial cell. Additionally, free extracellular hemoglobin may cause renal vasoconstriction through the local scavenging of nitric oxide within the renal arterioles.

Central Nervous System

Although charged entities such as copper ions do not readily cross the blood–brain barrier, elevated cerebrospinal fluid copper concentrations are characteristic of chronic copper overload conditions such as Wilson disease.¹¹² This accumulation is accomplished through carrier-mediated transport of albumin-bound, not ceruloplasmin-bound, copper into the central nervous system.

CLINICAL MANIFESTATIONS

Acute Copper Salt Poisoning

The acutely lethal dose of ingested copper sulfate is suggested to be 0.15 to 0.3 g/kg, but this is unverified. Gastrointestinal irritation is the most common initial manifestation of copper salt poisoning. This syndrome includes the rapid onset of emesis, abdominal pain, and less frequently gastroduodenal hemorrhage, ulceration, or perforation.^{6,28} Blue coloration of the vomitus may occur following the ingestion of certain copper salts, particularly copper sulfate.⁸¹ Blue vomitus is not, however, pathognomonic for copper poisoning and also occurs in patients who ingest boric acid, methylene blue, or food dyes. Other common symptoms include retrosternal chest pain and a metallic taste.

Given its location within the gastrointestinal tract, the liver receives the initial and most substantial exposure to any ingested copper. In the patients with more severe acute copper sulfate poisoning, hepatotoxicity is a frequent, although rarely an isolated,⁵⁵ manifestation. Jaundice, while among the most common clinical and biochemical findings following overdose, can be due to hepatocellular injury or hemolysis.⁸

Hemolysis is more common than hepatotoxicity, and occurs invariably in those patients with liver damage.¹⁰⁶ As noted, copper-induced hemolysis often occurs rapidly following exposure and may be severe (see Toxicology and Pathophysiology above and [Chap. 22](#)). In most reported cases, the discovery of significant methemoglobinemia occurs early in the clinical course and is rapidly followed by hemolysis. Because free methemoglobin is filterable, methemoglobinuria may occur, although it cannot be differentiated from other heme forms in the urine without specialized testing.

Kidney and lung toxicities occur occasionally and represent extraerythrocytic manifestations of the oxidative effects of the copper ions. In spite of massive intravascular hemolysis, hemoglobinuric kidney failure is uncommon in patients who receive adequate volume-replacement therapy.²⁶

Hypotension and cardiovascular collapse occur in patients with the most severe poisoning and is likely multifactorial in origin.¹⁰⁵ Undoubtedly, intravascular volume depletion from vomiting and diarrhea is involved. However, the severity and poor patient outcome despite appropriate volume repletion suggests that the direct effects of copper on vascular and cardiac cells are also involved. Sepsis, as a result of transmucosal bacterial invasion from the gastrointestinal tract, may also be partially responsible.⁶⁹

Depressed mental status, which ranges from lethargy to coma, or seizures following acute poisoning is likely an

epiphenomenon related to damage to other organ systems. An altered level of consciousness is particularly common in patients with hepatic failure, and the presentation is comparable to that of hepatic encephalopathy from other causes. In patients with chronic copper poisoning, such as Wilson disease, neurologic manifestations are prominent and typically involve movement disorders (see Chronic Copper Poisoning below).

Intravenous injection of copper sulfate reportedly produces a clinical syndrome identical to that which occurs following ingestion, although the gastrointestinal findings may be less pronounced.^{13,16,86} Subcutaneous administration of a veterinary copper glycinate solution produced skin necrosis in the area of the injection.^{9,87}

Although not strictly a form of copper poisoning, inhalation of copper oxide fumes generated during welding or other industrial processes may produce metal fume fever, a syndrome historically called “brass chills” or “foundry workers’ ague.” Patients with this syndrome present with cough, chills, chest pain, or fever that is most likely immunologic, and not toxicologic, in origin (Chap. 124). However, copper oxide formation, unlike zinc oxide, only occurs at extremely high temperatures, accounting for the relative infrequency of the copper-induced metal fume fever.

Chronic Copper Poisoning

Although hepatolenticular degeneration, known as Wilson disease, is a condition of chronic copper overload, there are qualitative similarities to acute copper poisoning. Wilson disease is an inherited, autosomal recessive disorder of copper metabolism affecting approximately 1 in 40,000 persons. The gene implicated in this disease (ATP7B) codes for a hepatocyte membrane-bound, copper-binding protein that is required for the maturation of ceruloplasmin and the biliary excretion of copper. Transgenic replacement models, in which human ATP7B is expressed in deficient animals, demonstrate normalization of copper excretion.⁷⁵ The absence of this gene, and the resultant increase in hepatic copper concentrations, produces continuing oxidative stress on the hepatocyte and cellular necrosis with the inevitable development of cirrhosis. Patients undergo periodic fluctuations in the extent of their copper-induced hepatotoxicity, and episodes of severe hepatotoxicity are frequently associated with hemolysis as stored copper is released from dying hepatocytes.

The adverse effects of copper on the lenticular nucleus in the basal ganglia cause movement disorders such as ataxia, tremor, parkinsonism, dysphagia, and dystonia.^{70,85} No other forms of copper poisoning are associated with substantial or direct neurotoxicity. Psychiatric manifestations, such as behavioral changes or mood disorders, may also occur. Accumulation of copper within the cornea accounts for the characteristic green-brown Kayser-Fleischer rings. Although the affected patient’s serum copper concentrations are decreased, the individuals typically have a reduced ceruloplasmin concentration and an elevated urinary copper concentration. Treatment involves lifelong therapy with D-penicillamine, trientine (triethylenetetramine), or molybdenum salts if the patient is D-penicillamine sensitive. Zinc acetate, approved by the US Food and Drug Administration (FDA) as a maintenance therapy, induces the formation of intestinal metallothionein and thereby blocks copper absorption by enhancing intestinal mucosal cell sequestration. Orthotopic liver transplantation results in improvement in nearly all aspects of the disease, including the central nervous system and ophthalmic manifestations.⁹⁶

Chronic exogenous copper poisoning is uncommon in adults but is reported following the use of copper-containing dietary supplements.⁸⁴ However, subacute or chronic exposure is common in children in some parts of the world. This condition, commonly called childhood cirrhosis in India or idiopathic copper toxicosis elsewhere, generally occurs following excessive dietary intake of copper due to copper contamination of milk from brass storage vessels. The affected children may have a genetic predisposition to copper accumulation, as signs of chronic liver disease develop by several months of age and progress rapidly thereafter.^{56,103} Both serum copper and ceruloplasmin concentrations are markedly elevated, which differentiates this disease from Wilson disease. The incidence of the disease has fallen dramatically, probably as a result of improved nutrition and replacement of utensils and storage containers containing copper with those made of steel. A family of four developed abdominal pain, malaise, tachycardia, and anemia after approximately one month of eating homegrown vegetables treated with copper oxychloride pesticide.⁴⁴ Each patient had anemia and a high normal or slightly elevated serum copper concentration.

“Vineyard sprayer’s lung,” first described in 1969, refers to the occupational pulmonary disease that occurred among Portuguese vineyard workers applying Bordeaux solution, a 1% to 2% copper sulfate solution neutralized with hydrated lime ($\text{Ca}(\text{OH})_2$).⁸⁹ The patients developed interstitial pulmonary fibrosis and histiocytic granulomas containing copper. Many of these workers also developed pulmonary adenocarcinoma, hepatic angiosarcoma, and micronodular cirrhosis, raising the possibility of a carcinogenic effect of chronic copper exposure.⁹⁰ There is also a suggestion of an increased incidence of pulmonary adenocarcinoma among smelters, who are, however, exposed to many other xenobiotics, including arsenic, a known carcinogen.⁷¹ Copper is not on the list of suspected carcinogens compiled by the International Agency of Research on Cancer.

Ophthalmic effects of copper salts, primarily following occupational exposure, include irritation of the corneal, conjunctival, or adnexal structures. Chronic ophthalmic exposure to particulate elemental copper or one of its alloys may result in chalcosis lentis, from the Greek word chalkos, or copper. This chronic exposure manifests as a green-brown

discoloration of the lens or cornea, similar to Kayser-Fleischer rings.

DIAGNOSTIC TESTING

Real-time testing for copper is impractical, and almost all management decisions must be based on clinical criteria. Copper concentrations are often obtained for confirmatory or investigative purposes. Although never adequately studied, whole-blood copper concentrations may correlate better with clinical findings than serum copper concentrations.²⁸ The rapid movement of copper from the serum into the erythrocyte presumably explains this finding. However, although there is a statistical relationship between the whole-blood copper concentrations and the severity of poisoning,^{28,118} there is little correlation between clinical findings at any given copper concentration, regardless of which biologic tissue is measured. Similarly, other than at extremely high or low concentrations, there is no defined concentration at which the prognosis may be established with certainty. Reported serum copper concentrations in patients with hemolysis range from 96 to 747 $\mu\text{g/dL}$, and reported concentrations in patients with severe poisoning are 6600 $\mu\text{g/dL}$ ⁴³ and 8267 $\mu\text{g/dL}$.²⁷ Serum copper concentrations in 11 patients with copper-induced acute kidney failure ranged from 115 to 390 $\mu\text{g/dL}$.²⁵ The urinary copper excretion per 24 hours is up to approximately 25 μg under normal circumstances and is reportedly as high as 628 $\mu\text{g}/24\text{ h}$ in patients with copper poisoning.

Occasionally, there is a secondary rise in serum copper concentrations, which likely results from release during hepatocellular necrosis. This secondary rise typically occurs in patients with life-threatening poisoning, and clinical evaluation is far more important and relevant than serial copper concentrations.¹⁰⁶

Elevated copper concentrations are also noted in patients with inflammatory conditions, biliary cirrhosis, pregnancy, and estrogenic oral contraceptive use.²¹ These conditions are associated with an elevated ceruloplasmin, and while the serum copper concentrations rise, the fraction of bound copper in the serum remains normal. Copper concentrations in the erythrocyte remain normal. Patients with Wilson disease have elevated hepatocyte copper content, but their serum copper concentrations are generally below normal unless hepatic necrosis is occurring.⁷²

Although serum ceruloplasmin concentrations rise in patients with acute copper poisoning,¹¹⁸ presumably reflecting increased hepatic synthesis, the ceruloplasmin concentration cannot be used to define prognosis. Tissue metallothionein concentrations may also rise following copper poisoning, but the implications of this finding, which is limited by the inability to rapidly obtain tissue samples, are unknown.⁶⁶ Ceruloplasmin concentrations are low in patients with Wilson disease, reflecting aberrant enzymatic activity.

Routine laboratory testing following acute copper salt poisoning should include an assessment for both intravascular hemolysis and hepatotoxicity. Differentiation of these etiologies as a cause for jaundice is made using standard methodologies, such as comparison of the bilirubin fractions and an assessment of the hepatic enzymes and hemoglobin; that is, indirect bilirubin is proportionally elevated in patients with hemolysis, whereas the direct fraction rises in patients with hepatocellular necrosis. The determination of intravascular hemolysis can be aided with the identification of a low serum haptoglobin or an elevated lactate dehydrogenase. An assessment of the patient's electrolyte and hydration status is warranted. The prothrombin time may be prolonged in the absence of liver injury or disseminated intravascular coagulopathy as a direct effect of free copper ions on the coagulation cascade.⁸⁰ In addition, many reports document an abnormal glucose 6-phosphate dehydrogenase (G6PD) activity, suggesting causation for hemolysis. However, interpretation of G6PD activity is difficult, because copper poisoning interferes with the measurement of G6PD.

Although copper metal embedded in the skin is clearly visible on radiography, topically applied copper salts are not visualized.¹⁵ The clinical usefulness of radiographs to identify ingested copper solutions has not been studied. Obtaining an abdominal radiograph, while probably of limited benefit, may be justified, because it occasionally demonstrates the presence of radiopaque material in the gastrointestinal tract. Early efforts to use magnetic resonance imaging to identify Wilson disease are underway.^{23,107}

MANAGEMENT

Supportive care is the cornerstone to the effective management of patients with acute copper poisoning, emphasizing antiemetic therapy, fluid and electrolyte correction, and normalization of vital signs prior to the consideration of chelation therapy. Gastrointestinal decontamination is of limited concern because the onset of emesis generally occurs within minutes of ingestion and is often protracted. In patients who present shortly after the ingestion of a liquid copper solution and who have not yet vomited, aspiration with a nasogastric tube may remove copper ions in solution or suspended in gastric materials. In one case, even after extensive vomiting, nasogastric aspiration still removed a blue solution, but removing this remaining volume is unlikely to provide significant clinical benefit.¹⁷ Although oral activated charcoal is unlikely to be harmful, it is of unproved benefit, and it may hinder the ability to perform gastrointestinal endoscopy to evaluate the corrosive effects of a copper salt on the mucosal surface.¹⁷ For this reason, even though activated charcoal may adsorb the

remaining copper in the proximal gastrointestinal tract, it is relatively contraindicated in most situations. Advanced therapy for patients with kidney failure may include hemodialysis, and for patients with life-threatening hepatic failure, liver transplantation may be needed.

Chelation Therapy

Chelation therapy should be initiated when hepatic, hematologic complications, or other concerning or severe manifestations of poisoning are present. Studies on the efficacy of chelation therapy following acute copper salt poisoning are limited. Even when administered early and appropriately, organ damage and death still occur. Application of the data from the existing literature is complex because of the lack of controlled studies of human copper poisoning. Although animal models and uncontrolled human data exist, the results are frequently contradictory. Three chelators are clinically available, and most data regarding dosing and efficacy data are derived either from chelator use in the treatment of patients with Wilson disease or from their effects on copper elimination during chelation of patients manifesting toxicity from other metals.

Most patients with copper poisoning are initially treated with intramuscular British anti-Lewisite (BAL).¹¹³ Although BAL may be less effective, its use is appropriate in patients in whom vomiting or gastrointestinal injury prevents oral D-penicillamine administration. Furthermore, because the BAL–copper complex primarily undergoes biliary elimination, whereas D-penicillamine undergoes renal elimination, BAL proves useful in patients with kidney failure. When tolerated, D-penicillamine therapy should be started simultaneously or shortly after the initiation of therapy with BAL (Antidotes in Depth: A25).

Calcium disodium ethylenediaminetetraacetate (CaNa_2EDTA) reduces the oxidative damage induced by copper ions in experimental models.¹²³ However, it does not greatly enhance the elimination of copper when used for the chelation of other metals.¹¹⁴ In addition, short-term use of CaNa_2EDTA inactivates dopamine β -hydroxylase in humans, presumably by chelating the copper moiety from its active site.³² However, because the *in vivo* activity of this enzyme is restored following the addition of exogenous copper, the potential for inhibition of the formation of neuronal norepinephrine during the treatment of acute poisoning is unknown. Successful clinical use of CaNa_2EDTA is reported.^{38,86,113} Interestingly, CuCaEDTA is used as a copper supplement in animals, and overdose of this formulation results in copper poisoning suggesting that its chelating ability is limited.³⁹ (See Antidotes in Depth: A27).

D-Penicillamine (Cuprimine), a structurally distinct metabolite of penicillin, is an orally bioavailable monothiol chelator. It is used in the treatment of lead, mercury, and copper toxicity, as well as in the management of rheumatoid arthritis and scleroderma. It has also more recently been investigated for its antiangiogenesis effects in cancer therapy, which occur by chelation of copper that serves as a cofactor for growth factors, such as fibroblast growth factor.¹¹⁵ D-Penicillamine is effective in preventing copper-induced hemolysis in patients with Wilson disease. Its protective mechanism is primarily mediated through chelation of unbound copper ions, rendering them unable to participate in redox reactions.⁶² The D-penicillamine–copper complex undergoes rapid renal clearance in patients with competent kidneys. The use of D-penicillamine is not formally studied in patients with acute copper salt poisoning, but case studies and animal models suggest that copper elimination is enhanced.^{18,41,51} In patients with Wilson disease, it dramatically increases the urinary elimination.¹¹⁷ The recommended adult dose is 1 to 1.5 g/d given orally in four divided doses, and although formal pediatric dosing recommendations are not available, some recommend the adult dose and others suggest 20 mg/kg/d orally every 12 hours.⁴⁹ D-Penicillamine is also indicated for the treatment of chronic exogenous copper poisoning, such as Indian childhood cirrhosis. Initiation early in the course of disease and discontinuation of the exposure to copper are associated with hepatic recovery and dramatically improved survival rates.¹²

Although D-penicillamine appears to be effective, it is associated with several significant complications. In nearly 50% of patients treated with D-penicillamine for Wilson disease, there is worsening of the neurologic findings.²⁰ Subacute toxicities of D-penicillamine include aplastic anemia, agranulocytosis, kidney and lung toxicity, and loss of trace metals.⁵⁴ Long-term use of D-penicillamine is also associated with the development of cutaneous lesions and immunologic dysfunction. However, in the brief treatment necessary for acutely poisoned patients, the major risk is the potential for hypersensitivity reactions that occur in 25% of patients who are allergic to penicillin. This hypersensitivity reaction is likely related to contamination of the pharmaceutical preparation with penicillin, rather than immunologic cross-reactivity.^{50,59} The use of D-penicillamine during pregnancy is associated with congenital abnormalities, although all of the data are derived from women with Wilson disease who were receiving long-term therapy.⁹¹

Succimer is sometimes described as an ineffective copper chelator, although it is able to triple the baseline copper elimination in a murine model. Given its ease of use, relative safety, and benefit in experimental models,¹ succimer may be used in lieu of D-penicillamine in patients with mild or moderate poisoning. Under these circumstances, the use of standard lead poisoning dosing regimens is warranted (Chap. 96 and Antidotes in Depth: A26).

DMPS, an experimental chelator that is gaining popularity for the treatment of arsenic poisoning, prevents acute tubular

necrosis in copper-poisoned mice.⁷⁸ DMPS also proved to be the most effective of a panel of chelators in a murine model of copper sulfate poisoning,⁵⁸ and it substantially increased urinary copper elimination in nonpoisoned, healthy individuals.¹¹⁶ However, DMPS, unlike D-penicillamine, forms intramolecular disulfide bridges, which liberates an electron. Although this accounts for its potency as a reducing agent, it also probably explains its propensity to worsen copper-induced hemolysis in vitro.² Because an adequate analysis of risk versus benefit is unavailable, DMPS should not be used to chelate copper-poisoned patients at this time.

Trientine (triethylenetetramine), an orally bioavailable chelator, is the second-line therapy for patients with Wilson disease, but its use in patients with acute copper poisoning is unreported. It has recently been studied for its role as a copper chelator in patients with Alzheimer disease.³¹ Zinc therapy to induce metallothionein synthesis, which is also of proven efficacy in Wilson disease, has an unknown role in the treatment of acute copper poisoning. The need for several weeks of zinc therapy prior to realizing full efficacy makes its therapeutic use in acutely poisoned patients questionable. Although large oral doses of zinc salts may limit the absorption of copper ion, the concomitant gastrointestinal irritant effects of zinc ion make this therapy impractical.

Tetrathiomolybdate, an FDA-recognized chelator with orphan drug status although not marketed, may be available through compounding pharmacies, typically as ammonium tetrathiomolybdate. In uncontrolled studies, tetrathiomolybdate is suggested to benefit copper-poisoned animals,⁸⁸ but its use in acute copper poisoning in humans is unstudied. Tetrathiomolybdate depleted the copper stores in a patient with cancer who purchased the compound over the Internet as an “alternative” antiangiogenesis therapy.⁶⁷

Clioquinol, a xenobiotic used 50 years ago as an antiparasitic, was discontinued due to epidemic optic neuropathy that may have been associated with its ability to chelate copper ions.¹⁰² Clioquinol is currently under investigation as a therapy for Alzheimer disease,¹⁰ but it has not been studied for patients with acute or chronic copper poisoning.

Extracorporeal Elimination

Limited data exist regarding the elimination of copper ions by various extracorporeal means. Hemodialysis membranes undoubtedly allow copper ions to cross, based on the epidemics in which hemodialysis using copper-rich water inadvertently resulted in copper poisoning.³⁵ Although copper should be similarly cleared by hemodialysis, its relatively large volume of distribution limits the potential clinical usefulness of this technique. Furthermore, copper ions are highly protein bound, and the dialyzable concentration is typically less than 1 pmol/L, suggesting that hemodialysis would have little clinical usefulness. This fact is supported by case reports in which serum, tissue, or dialysate concentrations of copper are assessed.^{4,86} Furthermore, given the propensity of hemodialysis to lyse erythrocytes, which may release stored copper and worsen toxicity, hemodialysis is not recommended except as indicated for kidney failure.

Molecular adsorbents recirculating system (MARS) and single-pass albumin dialysis (SPAD), modified forms of hemodialysis in which albumin is included in the dialysate, are reported to rapidly and substantially lower the serum copper concentrations in patients with fulminant Wilson disease, allowing a bridge to hepatic transplantation.^{24,30} A single patient with Wilson disease was treated with albumin dialysis using a 44 g/L albumin-containing dialysate and a slow dialysate flow rate (1–2 L/h) in a manner similar to routine continuous venovenous hemodiafiltration; this reportedly removed 105 mg of copper and normalized the serum copper concentration.⁶³ The risk associated with hemolysis likely remains, and caution should be used when extrapolating therapy from Wilson disease to exogenous copper poisoning.

Exchange transfusion is of undefined, but probably limited, benefit in acute copper sulfate poisoning.^{73,124} Plasma exchange enhanced the elimination of copper in patients with fulminant Wilson disease.^{61,63} Copper removal ranged from 3 to 12 mg per treatment, but it is unclear if either of these removal techniques would be beneficial following an ingestion of gram quantities of copper sulfate. The same warning as above about inadvertent red cell lysis applies.

Peritoneal dialysis is not useful in patients with fulminant Wilson disease.⁶⁵ Peritoneal dialysis removed less than 700 µg in a copper sulfate–poisoned child whose copper concentration was 207 µg/dL.⁴⁶ However, in the same patient, the addition of albumin to the dialysate removed 9 mg of copper at a time when the child’s serum copper concentration had already fallen substantially.

Management of the hepatic toxicity requires little more than standard supportive care. The potential benefit of N-acetylcysteine has not been studied, although it is useful in many forms of fulminant hepatic failure and is warranted in most hepatotoxic patients. Liver transplantation should be considered, but specific criteria for transfer to a specialized liver unit or for transplant, other than those that are applicable for Wilson disease or other more common etiologies of fulminant hepatic failure, are undefined.

There are no controlled data on the treatment of acute copper poisoning in pregnancy. The available data on pregnant women with Wilson disease document that D-penicillamine is teratogenic and that zinc may be the preferred therapy.

SUMMARY

- The toxic effects of copper are primarily mediated by oxidative stress on the erythrocyte and hepatocyte, and this similarity to iron salt poisoning adds a framework for the conceptual understanding of the disease.
- Chelation is most commonly performed with BAL and D-penicillamine.
- Succimer is more familiar to most clinicians and has fewer associated adverse effects; therefore, it is an acceptable alternative.
- Extracorporeal elimination is unlikely to be of benefit. Fortunately, exhaustive research into diseases of copper metabolism, particularly Wilson disease, which has periodic exacerbations similar to acute copper poisoning, has provided insight into managing patients with acute copper salt poisoning.

96 LEAD

Diane P. Calello and Fred M. Henretig

Lead (Pb)	
Atomic number	= 82
Atomic weight	= 207 Da
Normal concentration	
Whole blood	< 10 µg/dL (0.48 mmol/L)

HISTORY AND EPIDEMIOLOGY

Industrial Applications

The low melting point and high malleability of lead made it one of the first metals smelted and used by humans. Ancient Egyptians and Hebrews used lead, and the Phoenicians established lead mines in Spain circa 2000 B.C. The Greeks and Romans released lead during the process of extracting silver from ore. Roman society found many uses for lead, including pipes, cooking utensils, and ceramic glazes, and a common practice was to use sapa, a grape syrup simmered down in lead vessels, as a sweetener and preservative.¹¹⁸ Post-industrial lead use increased dramatically, and today lead is the most widely used nonferrous metal, with global extraction on the order of 9 million tons annually.⁸² Lead is used widely for its waterproofing and electrical-and radiation-shielding properties. Use of both lead-based paint for house paint and leaded gasoline has been essentially eliminated by regulation in the United States since the 1980s, but is still a concern in many nations, and persistence of lead paint in older US homes still constitutes an enormous environmental challenge.³

History of Lead-Related Health Effects

Dioscorides, a Greek physician in the second century B.C., observed adverse cognitive effects, and Pliny cautioned the Romans of the danger of inhaled fumes from lead smelting.¹¹⁴ Modern authors have suggested that extensive use of sapa in Roman aristocratic society contributed to the downfall of Roman dominance.¹¹⁸ Lead poisoning was also recognized in American colonial times. Benjamin Franklin observed in 1763 the “dry gripes” (abdominal colic) and “dangles” (wristdrop) that afflicted tinkers, painters, and typesetters, as well as the “gripes” caused by rum distillation in leaden condensing coils.¹⁰⁵ Lead salts, particularly lead acetate (sugar of lead), were used medicinally in the early 19th century to control bleeding and diarrhea. With the 19th century Industrial Revolution, lead poisoning became a common occupational disease. The reproductive effects of lead poisoning were recognized by the turn of the 20th century, including the high rate of stillbirths, infertility, and abortions among women in the pottery industry or who were married to pottery workers.

The modern history of childhood plumbism can be traced to the recognition of lead-paint poisoning in Brisbane, Australia, in 1897.¹¹⁴ Lead poisoning was reported in American children in 1917, and by 1943, it was established that children who recovered from clinical plumbism were frequently left with neurologic sequelae and intellectual impairment. Symptomatic childhood lead poisoning was a frequent occurrence in American pediatric medical centers throughout the 1950s and 1960s, a period during which research established effective chelation therapy protocols with British anti-Lewisite (BAL) and edetate calcium disodium (CaNa₂EDTA).³⁴ From the 1970s to the present, the research thrust in childhood lead poisoning has centered on the recognition and quantification of more subtle neurocognitive impairment caused by subclinical lead poisoning.^{16,115} Over this time period, the US Centers for Disease Control and Prevention (CDC) has steadily revised downward the definitions of a normal blood lead concentration (BLL) in children. The CDC definition of childhood lead poisoning was 60 µg/dL in the early 1960s, was reduced to 10 µg/dL in 1991,²² and in recent years has been further revised in light of evidence suggesting adverse cognitive effects in young children at BLLs below 10 µg/dL.²⁰ The most recent CDC Advisory Council on Childhood Lead Poisoning recommendations lower the “level of concern” to 5 µg/dL and eliminate the term “threshold,” in response to emerging data demonstrating a supralinear dose-response curve for intelligence quotient (IQ) decrement at even the lowest detectable BLLs.^{8,27,79,88}

Sources of Human Exposure

Numerous sources of lead exposure exist and can be generally classified as environmental, occupational, or additional (some what “exotic”) sources. Environmental exposures affect the entire population, particularly young children. These occur primarily by exposure to lead paint in the United States (Table 96–1). Because of its continuing impact in the United States today, lead paint exposure is further detailed here.

TABLE 96–1. Environmental Lead Sources

Source	Comment
Paint	Especially pre-1978 homes
Dust	House dust from deteriorated lead paint
Soil	From yards contaminated by deteriorated lead paint, lead industry emissions, roadways with high leaded gasoline usage
Water	Leached from leaded plumbing (pipes, solder), cooking utensils, water coolers
Air	Leaded gasoline (pre-1976 United States; still prevalent worldwide), industrial emissions
Food	Lead solder in cans (pre-1991 United States; still prevalent in imported canned foods); “natural” dietary supplements; “moonshine” whiskey and lead foil–covered wines; contaminated flour, paprika, other imported foods and candy; lead leached from leaded crystal, ceramics, vinyl lunch boxes
Other	Complementary and alternative medicines, children’s toys and jewelry (especially imported products), cosmetics, leaded ink, vinyl mini-blinds

Lead pigments (typically lead carbonate) account for 50% by weight of many white house paints from the pre–World War II era. Since 1978, paint intended for interior or exterior residential surfaces, toys, or furniture in the United States may contain, by law, no more than 0.06% lead. However, an estimated 3 million tons of lead remain in 57 million US homes built before 1980 and painted with lead-based paint. This aging housing stock has created an enormous environmental hazard of lead exposure to children and to adult homeowners, house painters, and construction workers who become involved in sanding, scraping, and restoration of painted surfaces in these homes. Furthermore, lead-based paint is still allowed for industrial, military, marine, and some outdoor uses, such as structural components of bridges and highways; occasionally, some of this paint is inadvertently used in homes.²³ Attempts to abate lead-painted outdoor structures can pollute entire communities.⁸⁷

Although paint-derived lead exposure may result from pica in some children, most lead paint exposure in childhood relates to the crumbling, peeling, flaking, or chalking of aging paint.²² These fine paint particles are incorporated into household dust and yard soil, where ordinary childhood hand–mouth activity results in ingestion.²⁹ Seasonal variations in house dust contamination occur, with higher house dust lead concentrations and increased BLLs in exposed preschool children noted during the summer.

Adults with occupational exposures to lead constitute another large group of persons at risk. It is estimated that more than 1 million workers in the United States, employed in more than 100 occupations, are exposed to lead.¹⁴⁰ The most important route of absorption in occupational settings is inhalation of lead dust and fumes. In addition, ingestion may result when workers eat, drink, or smoke in lead dust–contaminated areas. However, the presence of lead in the workplace, per se, does not imply a significant risk of poisoning. Some types of lead-related work are more hazardous than others (Table 96–2).^{140,147} For example, lead smelting can be categorized as primary (from raw ore) and secondary (reclamation, such as from used car batteries). Secondary lead production workers may be at higher risk of poisoning because this job more typically involves small, sometimes “backyard” operations that are less likely to adhere to industry safety regulations than large, well regulated primary smelters.⁴¹

TABLE 96–2. Occupational and Recreational Lead Sources

High Risk Occupations

Automobile radiator repairers

Crystal glass makers

Firing range instructors, bullet salvagers

Lead smelters, refiners

Metal welders, cutters (includes bridge and highway reconstruction workers)

Painters, construction workers (sanding, scraping, or spraying of lead paint; demolition of lead-painted sites)

Polyvinyl chloride plastic manufacturers

Shipbreakers

Storage battery manufacturers, repairers, recyclers

Moderate Risk Occupations

Automobile factory workers and mechanics

Enamellers

Glass blowers

Lead miners

Plumbers

Pottery glazers

Ship repairers

Shot makers

Solderers

Type founders

Varnish makers

Wire and cable workers

Possible Increased Risk Occupations

Electronics manufacturers

Jewelers

Pipefitters

Printers

Rubber product manufacturers

Traffic police officers, taxi drivers, garage workers, turnpike tollbooth operators, gas station attendants (exposed to leaded gasoline exhaust fumes; unlikely now in the United States but still a hazard in developing countries)

Recreational and Hobby Sources

Ceramic crafts

Furniture refinishing, restoring

Home remodeling, refinishing

Painting (fine artist's pigments)

Repair of automobiles, boats

Stained glass making

Target shooting, recasting lead for bullets

Additional sources

Ingested lead foreign bodies and retained lead bullets

Illicit substance abuse (heroin, methamphetamine, leaded gasoline "huffing")

Burning batteries, leaded paper, or wood for fuel

Hand-mouth contact with pool cue chalk, glazes, leaded ink

For convenience, environmental and occupational or recreational lead exposures are discussed separately, although there is considerable overlap. For example, workers who fail to change lead dust-covered work clothes or shoes may bring this occupational lead hazard home and secondarily contaminate their children's environment.¹⁴⁰

Finally, numerous additional sources of lead exposure are also reported, including contaminated folk medications or cosmetics,^{19,21,89,143} imported food,⁶⁶ ingested lead foreign bodies,^{102,106,172} and retained bullets.^{50,94,148} Since 2010, an outbreak of lead encephalopathy from artisanal gold mining in Nigeria has claimed hundreds of lives, with the toll still growing.^{11,44}

Some potential exposures have raised considerable community concern and media coverage in recent years—for example, the discovery of lead contamination of some artificial turfs²³ and imported toys coated with lead paint.⁹⁵ These, too, are highlighted separately in [Table 96–2](#).

Prevalence

Several recent national and regional surveys have evaluated current US population-based trends in BLLs and sociodemographic correlates. The CDC estimates that approximately 450,000 children aged 1 to 5 years have BLLs greater than 5 µg/dL,²⁷ the 2012 revised reference value representing primarily excessive household exposure, and that approximately 8000 adults are reported each year with BLLs greater than 24 µg/dL (typically reflecting excessive occupational exposure).¹⁷ Although such numbers are impressive, they represent a considerable decrease from prevalence rates reported in prior decades (eg, from 8.6% of children with elevated BLLs from 1988 to 1991 to 1.4% from 1999 to 2004),⁷⁷ and it is certainly the observed clinical experience that symptomatic lead poisoning in children, in particular, is far less common than it was a generation ago. Nevertheless, for young minority children and poor people who reside in the deteriorating central cities of the United States, the battle is far from won. For example, the CDC reported in 2000 that children enrolled in Medicaid had a prevalence of elevated BLLs three times greater than those not enrolled.²⁵ Refugee, immigrant, and foreign-born adopted children remain at particularly high risk,^{18,89} and remarkable cases of extremely elevated BLLs (>100 µg/dL) may still be detected on routine screening.⁴⁰

PHYSICAL PROPERTIES

Lead is a silvery-gray, soft metal ubiquitous element in the earth's crust, with an atomic weight of 207.21 Da and an atomic number of 82. It has a low melting point, 621.3°F (327.4°C), and boils at 2948°F (1620°C) at atmospheric pressure.¹⁷¹ It occurs principally as two isotopes: ²⁰⁶Pb and ²⁰⁸Pb. Metallic lead is relatively insoluble in water and dilute acids but dissolves in nitric, acetic, and hot, concentrated sulfuric acids. In compounds, lead assumes valence states of +2 and +4. Inorganic lead compounds may be brightly colored and vary widely in water solubility; several are used extensively as pigments in paints such as lead chromate (yellow) and lead oxide (red). Lead also forms organic compounds, of which two, tetramethyl and tetraethyl lead (TEL), were used commercially as gasoline additives.⁸² These are essentially insoluble in water but readily soluble in organic solvents.¹⁴⁴ Lead complexes with ligands containing sulfur, oxygen, or nitrogen as electron donors. It thus forms stable complexes with several ligands common to biologic molecules, including –OH, –SH, and –NH₂. Complexes with endogenous sulfhydryl (–SH) groups are thought to be the most toxicologically important. There is no known physiologic role for lead, and thus any lead presence in human tissue represents contamination.

TOXICOLOGY

Toxicokinetics

Inorganic and Metallic Lead. Absorption. Gastrointestinal (GI) absorption is less efficient than pulmonary absorption. Adults absorb an estimated 10% to 15% of ingested lead in food, and children have a higher GI absorption rate, averaging 40% to 50%.^{1,58} In animal studies, this varies by type of lead compound studied.⁶ However, it should be noted that fasting and diets deficient in iron, calcium, and zinc—factors that are frequent among groups of young children—enhance GI absorption of lead.^{58,97} The role of essential trace elements in decreasing lead absorption is assumed to be a consequence of competitive absorption processes. Metallic lead is also absorbed, albeit less readily than most lead compounds.⁶ The rate of absorption of metallic lead appears to be related to particle size, total surface area, and GI tract location; whereas gastric acidity favors dissolution, the small bowel is likely the site of maximal absorption.^{102,106,172}

The overall absorption of inhaled lead averages 30% to 40%. Of note, both minute ventilation and the concentration of lead in air determine airborne lead exposure, so a worker engaged in vigorous physical activity will absorb considerably more lead than a person in the same atmosphere at rest. Likewise, children, having a relatively greater volume of inhaled air per unit of body size because of higher metabolic rates, are proportionally at greater risk in a given degree of atmospheric lead pollution. It is estimated that children have a 2.7-fold higher lung deposition rate of lead than do adults.¹

Cutaneous absorption of inorganic lead is low; one study found an average absorption of 0.06% through intact skin.¹⁰⁹ Soft tissue absorption of metallic lead follows exposure to retained bullets, and similar to ingested lead foreign bodies, also depends on particle size, total surface area, and location; multiple small shot and location in which particles are bathed by synovial, serosal, or spinal fluid favor a more rapid increase in BLL.^{50,94,148} This is thought to be due to increased solvency of lead in organic acids, such as hyaluronic acid in synovial fluid, as well as mechanical forces from joint motion.

Transplacental lead transfer is critical in fetal and neonatal lead exposure. Lead readily crosses the placental barrier throughout gestation, and lead uptake is cumulative until birth.¹³¹

Distribution. Absorbed lead enters the bloodstream, where at least 99% is bound to erythrocytes.⁵⁹ From blood, lead is distributed into both a relatively labile soft tissue pool and into a more stable bone compartment. This classic three-compartment model may be some what of an oversimplification. Currently, at least two bone compartments are recognized: a more labile pool in trabecular bone and a more stable pool in cortical bone. In adults, approximately 95% of the body lead burden is stored in bone versus only 70% for children. The remainder is distributed to the major soft tissue lead-storage sites, including the liver, kidney, bone marrow, and brain. Lead uptake into soft tissues occurs in a complex fashion that depends on numerous factors, including blood lead concentrations, external exposure factors, and specific tissue kinetics. Most of the toxicity associated with lead is a result of soft tissue uptake, so that the relative decrease in bone storage is another comparative disadvantage for children.

Lead in the central nervous system (CNS) is of particular toxicologic importance. Lead preferentially concentrates in gray matter and certain nuclei.⁵⁹ Fetal brain uptake is relatively higher than with postnatal exposure in animal models. The highest brain concentrations are found in the hippocampus, cerebellum, cerebral cortex, and medulla.

Unlike soft tissue storage, bone lead accumulates throughout life. Bone storage begins in utero and occurs across all ranges of exposure, so that there is no threshold for bone lead uptake.¹ Total body accumulation of lead may range from 200 to 500 mg in workers with heavy occupational exposure.⁵⁹ Bone lead is thought to be relatively metabolically inert, but it can be mobilized from the more labile compartments and contributes as much as 50% of the blood lead content. This may be of particular importance during times of rapid bone turnover such as pregnancy and lactation, in elderly persons with osteoporosis,¹⁵⁶ and in children with immobilization.¹⁰³ Lead also accumulates in the teeth, particularly the dentine of children's teeth, a phenomenon that has been used to quantify cumulative lead exposure in young children.¹¹⁵

Excretion. Absorbed lead that is not retained is primarily excreted in urine (approximately 65%) and bile (approximately 35%).¹ A miniscule amount is lost via sweat, hair, and nails. Children excrete less of their daily uptake than adults, with an average retention of 33% versus 1% to 4%, respectively.¹⁸² Biologic half-lives for lead are estimated as follows: blood (adults, short-term experiments), 25 days; blood (children, natural exposure), 10 months; soft tissues (adults, short-term exposure), 40 days; bone (labile, trabecular pool), 90 days; and bone (cortical, stable pool), 10 to 20 years.^{1,99,132} Trace amounts of lead are also excreted in breast milk.⁷

Organic Lead. Alkyl lead compounds are lipid soluble and have unique pharmacokinetics that are less well characterized than those of inorganic lead.⁹ Animal studies and human clinical experience with acute ingestions and leaded gasoline sniffing demonstrate TEL absorption through ingestion; inhalation; and intact skin and subsequent distribution to lipophilic tissues, including the brain.^{144,164,180} TEL is metabolized to triethyl lead, which is believed to be the major toxic compound. Alkyl leads may slowly release lead as the inorganic form, with subsequent kinetics as noted above.⁹

PATHOPHYSIOLOGY

General Mechanisms

Similar to many metals, lead is a complex xenobiotic exerting numerous pathophysiologic effects in many organ systems.⁵⁹ Furthermore, genetic polymorphism may impact on individual susceptibility to lead.¹¹⁹ Recently identified examples of such include the genes for apolipoprotein E, the vitamin D receptor, Na⁺-K⁺-ATPase, δ -aminolevulinic acid, and protein kinase C.¹⁴⁶ At the biomolecular level, lead functions in three general ways. First, its affinity for biologic electron-donor ligands, especially sulfhydryl groups, allows it to bind and impact numerous enzymatic, receptor, and structural proteins. Second, lead is chemically similar to the divalent cations calcium and zinc and interferes with numerous calcium-(and perhaps zinc-) mediated metabolic pathways, particularly in mitochondria and in second-messenger systems regulating cellular energy metabolism.⁹⁰ Lead-induced mitochondrial injury may result in apoptosis, a phenomenon particularly well studied in animal models of retinal cells.⁹⁰ Lead may function as an inhibitor or agonist of calcium-dependent processes. For example, lead inhibits neuronal voltage-sensitive calcium channels⁶ and membrane-bound Na⁺-K⁺-ATPase (adenosine triphosphatase)¹⁵⁸ but activates calcium-dependent protein kinase C.¹⁰¹ These effects adversely impact neurotransmitter function.¹⁷⁶ Third, lead exhibits mutagenic and mitogenic effects in mammalian cells in vitro and is carcinogenic in rats and mice.⁴⁵ There is mechanistic plausibility and some epidemiologic evidence for at least a facilitative role of lead in human carcinogenesis,⁷¹ and the International Agency for Research on Cancer (IARC) has assigned inorganic lead compounds a group 2A (probably carcinogenic to humans) classification.^{72,155}

Neurotoxicity

The neurotoxicity of lead involves multiple targets, including cerebrovascular endothelium, mitochondria, neural cell adhesion molecules, neurotransmitter and second-messenger function, regulation of apoptosis, and myelin formation.^{90,133,176} Lead-induced dysfunction in several neurotransmitter systems is linked to its calcium-mimetic properties. Through blockade of calcium influx at voltage-sensitive calcium channels, lead inhibits depolarization-triggered release of acetylcholine, dopamine, and γ -amino butyric acid (GABA) but augments the background rate of spontaneous release.^{36,59,76,90,176} The dampening of the evoked neurotransmitter response in conjunction with enhanced background release results in a decreased “signal-to-noise” ratio.^{56,76} In addition, lead decreases calcium currents at the N-methyl-D-aspartate (NMDA) glutamate receptor and directly activates the intracellular second-messenger protein kinase C.⁷⁶ These effects on neurotransmitter release, receptor activity, and intracellular signaling adversely affect “synaptic pruning” in the developing brain, a process by which the volume of excessive synaptic connections is selectively reduced. This disruption results in suboptimal cortical microarchitecture and function, and it particularly affects the hippocampus, an important locus of learning and memory.^{56,76,176}

Lead also interferes with the 78-kDa chaperone glucose-regulated protein (GRP78) in astrocytes, which may result in adverse protein conformational effects that are thought to be associated with conditions such as Alzheimer disease.¹⁷⁶ In severe cases, pathologic changes in cerebral microvasculature may result in cerebral edema and increased intracranial pressure (ICP), which are associated with the clinical syndrome of acute lead encephalopathy (Fig. 96–1). Peripheral neuropathy is a classic effect of lead poisoning in adults. The neuropathology in humans is poorly characterized. In animal models, it is associated with Schwann cell destruction, segmental demyelination, and axonal degeneration.⁵⁹ Sensory nerves are less affected than motor nerves.

FIGURE 96–1. Computed tomography scan of the brain reveals diffuse cerebral edema and loss of gray-white matter differentiation on day 1 of hospitalization of a 3 year-old boy. He had presented with a brief prodrome of vomiting and altered mental status followed by status epilepticus, characteristic of acute lead encephalopathy. His blood lead concentration was 220 $\mu\text{g/dL}$. (Used with permission of Department of Radiology, St. Christopher’s Hospital for Children, Philadelphia, PA.)

Hematologic Toxicity

Lead is hematotoxic in several ways, including via potent inhibition of several enzymes in the heme biosynthetic pathway (Chap. 22 and Fig. 22–3). It also induces a defect in erythropoietin function secondary to associated kidney damage.^{64,139} A shortened erythrocyte life span is caused by increased membrane fragility with resultant hemolysis. Inhibition of $\text{Na}^+\text{-K}^+\text{-ATPase}$ and pyrimidine-5'-nucleotidase may impair erythrocyte membrane stability by altering energy metabolism. The inhibition of pyrimidine-5'-nucleotidase is also thought to underlie the appearance of basophilic stippling in erythrocytes, representing clumping of degraded RNA, which is normally eliminated by this enzyme¹²¹ (Fig. 96–2).

FIGURE 96–2. This peripheral smear of blood examined under high-power microscopy demonstrates the classic basophilic stippling associated with lead poisoning. The patient’s blood lead concentration was over 100 µg/dL. (Used with permission of The New York City Poison Center Toxicology Fellowship Program).

Nephrotoxicity

Functional changes associated with acute lead nephropathy include decreased energy-dependent transport, resulting in a Fanconilike syndrome of aminoaciduria, glycosuria, and phosphaturia. These changes are related to disturbed mitochondrial respiration and phosphorylation and are reversible with discontinuation of exposure or treatment.⁶¹ A pathologic finding is characteristic nuclear inclusion bodies in renal tubular cells composed of lead–protein complex. Chronic high-dose lead poisoning is associated with progressive interstitial fibrosis.⁸⁶ Lead is a renal carcinogen in rodent models, but its status in humans is uncertain.^{45,59}

The association of plumbism with gout (“saturnine gout”) was noted more than 100 years ago. Lead competitively decreases uric acid excretion in the distal tubule, resulting in elevated blood urate concentrations and urate crystal deposition in joints. Kidney function is virtually always impaired in patients with saturnine gout.

Cardiotoxicity

The most important manifestation of lead toxicity on the cardiovascular system is hypertension. This is likely caused by altered calcium-activated changes in contractility of vascular smooth muscle cells secondary to decreased Na^+ - K^+ -ATPase activity and stimulation of the Na^+ - Ca^{2+} exchange pump. Lead may also affect blood vessels by altering neuroendocrine input or sensitivity to such stimuli or by increasing reactive oxygen species that enhance nitric oxide inactivation.⁹³ Elevated serum renin activity is found with moderate toxicity but may be normal or decreased in chronic severe plumbism.¹⁷³ Rarely, direct cardiotoxicity is reported.^{114,135,157} Animal models demonstrate increased sensitivity to norepinephrine-induced dysrhythmias and decreased myocardial contractility, protein phosphorylation, and high-energy phosphate generation.⁸³ Lead-induced impairment of intracellular calcium metabolism may impact cardiac electrophysiology.

Reproductive Toxicity

Impairment of both male and female reproductive function is associated with overt plumbism. Gametotoxic effects in animals of both sexes and chromosomal abnormalities in workers with BLLs above 60 µg/dL are reported.⁵⁹ Testicular endocrine hypofunction occurs in smelter workers with BLLs in the 60 µg/dL range.¹³⁷

Endocrine Toxicity

Reduced thyroid and adrenopituitary function are found in adult lead workers.^{53,142} Children with elevated BLLs have a depressed secretion of human growth hormone and insulinlike growth factor.⁷⁰

Skeletal Toxicity

In addition to the importance of the skeletal system as the largest repository of lead body burden, studies suggest that bone metabolism also is adversely affected by lead.⁵⁹ Hormonal response is altered by reduced 1,25-dihydroxyvitamin D₃ concentrations and by inhibition of osteocalcin. Both new bone formation and coupling of normal osteoblast and osteoclast function may thus be impaired.⁵⁹ Bands of increased metaphyseal density on radiographs of long bones (“lead lines”) in young children with heavy lead exposure represent increased calcium deposition (not primarily lead) in the zones of provisional calcification (**Fig. 96–3**). Impaired bone growth and shortened stature are associated with childhood lead poisoning. Impaired calcium or cyclic adenosine monophosphate (cAMP) messenger systems may underlie these cellular effects.

FIGURE 96–3. (A) Radiograph of the wrist reveals increased bands of calcification (“lead lines”) in the same patient as in **Fig. 96–1**. (B) Similar radiographic findings in another patient at the knee. (Part A used with permission of Department of Radiology, St. Christopher’s Hospital for Children, Philadelphia, PA. Part B used with permission of Richard Markowitz, MD, Department of Radiology, Children’s Hospital of Philadelphia, Philadelphia, PA.)

Gastrointestinal Toxicity

Lead toxicity causes constipation, anorexia, and colicky abdominal pain. Although the mechanisms are not fully elucidated, theories include impaired intestinal motility, alterations in luminal ion transport, and spasmodic contraction of intestinal wall smooth muscle.^{39,144}

CLINICAL MANIFESTATIONS

Inorganic Lead

The numerous observed lead-induced pathophysiologic effects accurately predict that the clinical manifestations of lead poisoning are diverse. These manifestations of lead toxicity are characterized into distinct acute and chronic syndromes (**Tables 96–3 and 96–4**). In most cases, these distinctions really describe a continuum of dose-and time-related severity. Rarely, patients with massive acute poisoning present with clinical findings that are somewhat unique but overlap considerably with cases of severe chronic plumbism. However, it should be first reemphasized that the occurrence of overt clinical effects in lead poisoning is, in most cases, the culmination of a long-term lead exposure. As the total dose increases, these effects are almost always preceded first by measurable biochemical and physiologic impairment followed, in turn, by subtle prodromal clinical effects that may only become apparent in hindsight. In general, children are considered to be more susceptible than adults to toxicity for a given measured BLL; however, the data for this primarily concern effects on the CNS.

TABLE 96–3. Clinical Manifestations of Lead Poisoning in Children

<i>Clinical Severity</i>	<i>Typical Blood Lead Concentrations (µg/dL)</i>
Severe CNS: Encephalopathy (coma, altered sensorium, seizures, bizarre behavior, ataxia, apathy, incoordination, loss of developmental skills, papilledema, cranial nerve palsies, signs of increased ICP) GI: Persistent vomiting Hematologic: Pallor (anemia)	>70–100
Mild to moderate CNS: Hyperirritable behavior, intermittent lethargy, decreased interest in play, “difficult” child GI: Intermittent vomiting, abdominal pain, anorexia	50–70
Asymptomatic CNS: Impaired cognition, behavior, balance, fine-motor coordination Miscellaneous: Impaired hearing, impaired growth	>49

CNS = central nervous system; GI = gastrointestinal; ICP = intracranial pressure.

TABLE 96–4. Clinical Manifestations of Lead Poisoning in Adults

<i>Clinical Severity</i>	<i>Typical Blood Lead Concentrations (µg/dL)</i>
Severe CNS: Encephalopathy (coma, seizures, obtundation, delirium, focal motor disturbances, headaches, papilledema, optic neuritis, signs of increased ICP) PNS: Foot drop, wrist drop GI: Abdominal colic Hematologic: Pallor (anemia) Renal: Nephropathy	>100
Moderate CNS: Headache, memory loss, decreased libido, insomnia PNS: peripheral neuropathy GI: Metallic taste, abdominal pain, anorexia, constipation Kidney: Arthritis due to saturnine gout (impaired urate excretion) Miscellaneous: Mild anemia, myalgias, muscle weakness, arthralgias	70–100
Mild CNS: Fatigue, somnolence, moodiness, lessened interest in leisure activities Miscellaneous: Adverse effects on cognition, reproduction, kidney function, or bone density; hypertension and cardiovascular disease; possible increased risk of cancer	20–69 ^a

^aChronic lead exposure at lower blood lead concentrations may lead to cumulative body burdens of lead associated with these clinical findings.

CNS = central nervous system; GI = gastrointestinal; ICP = intracranial pressure; PNS = peripheral nervous system.

Asymptomatic Children. Children with elevated body lead burdens but without overt symptoms represent the largest group of persons believed to be at risk for chronic lead toxicity. The subclinical toxicity of lead in this population centers around subtle effects on growth, hearing, and neurocognitive development. This last effect, in particular, is the subject of intense research interest and scrutiny. An effort to rigorously evaluate several modern (since 1979), carefully performed studies of the association of low lead and reduced intelligence (cross-sectional studies with blood or tooth lead and prospective studies) and combine their results with a statistical meta-analysis technique is reported.¹²⁷ The overall finding was that even though the majority of individual studies failed to achieve statistical significance, in pooled analysis there was a significant inverse association between lead exposure and IQ. The magnitude was on the order of 1 to 2 IQ points for chronic BLL increases from 10 to 20 µg/dL. Since that publication, another study evaluated IQ in children from 6 months to 5 years of age and found that BLLs were inversely correlated with IQ at 3 and 5 years of age and that the magnitude of effect for all subjects was an average 4.6 point decrement in IQ for each 10 µg/dL increase in BLL. Of particular concern, this effect was even greater, with an estimated 7.4 point loss, for the subset of children in the 1 to 10 µg/dL BLL range.¹⁶ The CDC recently compiled a number of studies confirming this steeper dose response at BLLs below 10 µg/dL²⁰ and revised screening guidelines to remove the term “threshold” and lower the action BLL to 5 µg/dL, a reference value to be evaluated every 4 years based on the 97.5 percentile in most recent NHANES data.^{27,88}

Symptomatic Children. Subencephalopathic symptomatic plumbism usually occurs in children 1 to 5 years of age and is associated with BLLs above 70 µg/dL but may occur with concentrations as low as 50 µg/dL. Unfortunately, common complaints in well children of this age (eg, the “terrible twos,” with functional constipation and who do not eat as much as parents expect) often overlap with the milder range of reported symptoms of lead poisoning. Frequently, parents of children diagnosed by routine blood screening recognize milder symptoms only in hindsight after chelation treatment results in

clinical improvement (“it seemed as if the child was going through a phase”)⁵⁴ This is especially true currently, when symptomatic plumbism is rarely reported.^{19,22} Other uncommon clinical presentations are described, including isolated seizures without encephalopathy (indistinguishable from idiopathic epilepsy), chronic hyperactive behavior disorder, isolated developmental delay, progressive loss of cortical function simulating degenerative cerebral disease, peripheral neuropathy (reported particularly in children with sickle cell hemoglobinopathy), and the occurrence of GI effects (colicky abdominal pain, vomiting, constipation) with myalgias of the trunk and proximal girdle muscles.^{34,46}

Acute lead encephalopathy is the most severe presentation of pediatric plumbism (Table 96–3). It may be associated with cerebral edema and increased ICP (Fig. 96–1). Encephalopathy is characterized by pernicious vomiting and apathy, bizarre behavior, loss of recently acquired developmental skills, ataxia, incoordination, seizures, altered sensorium, or coma. Physical examination may reveal papilledema, oculomotor or facial nerve palsy, diminished deep tendon reflexes, or other evidence of increased ICP.^{19,178} Encephalopathy usually occurs in children ages 15 to 30 months; is associated with BLLs above 100 µg/dL, although it is reported with BLLs as low as 70 µg/dL; and tends to occur more commonly in summer months, when BLLs peak.¹²⁵ Milder but ominous findings that may portend incipient encephalopathy include anorexia, constipation, intermittent abdominal pain, sporadic vomiting, hyperirritable or aggressive behavior, periods of lethargy interspersed with lucid intervals, and decreased interest in play activities. Many such patients seek medical advice for vomiting and lethargy during the 2 to 7 days before onset of frank encephalopathy.^{34,125} Physical examination of such children usually reveals no specific abnormalities.

Mortality caused by encephalopathy was 65% in the prechelation era, decreasing to below 5% with the advent of effective chelation. The incidence of permanent neurologic sequelae, including mental retardation, seizure disorder, blindness, and hemiparesis, is 25% to 30% in patients who develop encephalopathic symptoms before the onset of chelation (Fig. 96–4).³⁴

FIGURE 96–4. Magnetic resonance image of the brain reveals cortical atrophy and multiple areas of cerebral infarction in the same patient as in Fig. 96–1, done on hospital day 22. At this time, the child’s clinical status was notable for choreoathetoid movements and generalized hypotonia, inability to localize visual or auditory stimuli, and nonpurposeful movements of the extremities. (Used with permission of Eric Faerber, MD, Department of Radiology, St. Christopher’s Hospital for Children, Philadelphia, PA.)

Adults. Adults with occupational lead exposure may manifest numerous signs and symptoms representing disorders of several organ systems. Severity of symptoms correlates roughly with BLLs, although many conditions thought to be

associated with low-dose chronic lead exposure are better correlated with markers of cumulative dose, such as bone lead or the cumulative blood lead index (area under the curve of BLLs versus time).^{69,86} (Table 96–4). True acute poisoning occurs rarely, after very high inhalational,⁸² large oral,¹¹⁶ or intravenous (IV) exposures.¹¹⁷ Such patients may present with colicky abdominal pain, hepatitis, pancreatitis, hemolytic anemia, and encephalopathy over days or weeks. Most adult plumbism is related to chronic respiratory exposure, although some authors have used the term “acute poisoning” to include patients with such exposure whose symptoms are severe and of relatively recent onset (within 6 weeks of presentation) and whose exposure is relatively brief (average, one year or less).³⁸

In severe plumbism, the hallmark of toxicity is acute encephalopathy, which has been rarely reported in adults since the 1920s.³⁸ The majority of modern cases are actually not associated with occupational exposures but rather with more exotic exposures, such as ingestion of lead-contaminated illicit “moonshine” whiskey and ethnic alternative medications.^{81,161} Encephalopathy in adults is usually associated with very high BLLs (typically >150 µg/dL) and is manifested by seizures (75% of cases), obtundation, confusion, focal motor disturbances, papilledema, headaches, and optic neuritis.^{104,177} In addition, adult patients with severe plumbism often manifest attacks of abdominal colic, are virtually always anemic, and are at significant risk for severe peripheral neuropathy that manifests as wristdrop and footdrop. Nephrotoxic effects may include a Fanconilike syndrome, impaired kidney function, and progressive interstitial fibrosis. Rarely, ventricular dysrhythmias are reported, and long-standing lead toxicity is associated with prolonged QT and QRS intervals.^{49,135}

Moderate plumbism in adults typically involves CNS, peripheral nerves, hematologic, kidney, GI, rheumatologic, endocrine or reproductive, and cardiovascular findings.^{82,140,144} At BLLs above 70 µg/dL, such symptoms may include headache, memory loss, decreased libido, and insomnia. GI symptoms may include metallic taste, abdominal pain, decreased appetite, weight loss, and constipation. Abdominal guarding and tenderness are occasionally observed. Musculoskeletal and rheumatologic complaints at this stage include muscle pain and joint tenderness. Patients with saturnine gout may have typical joint findings of acute arthritis. Peripheral neuropathy may occur, primarily motor, manifesting as dominant hand or wrist weakness, numbness of the legs, paresthesias, and tremor. Many patients at this stage have mild anemia, and those with chronic exposure are at risk for neuropathy as described above.

Mild plumbism may manifest as minor CNS findings, such as changes in mood and cognition. Subtle abnormalities detectable by careful neuropsychiatric testing are found in both adults and children with modest elevations in BLLs and include impaired memory span, rapid motor tapping, visual motor coordination, and grip strength.³⁸ Studies document abnormal psychometrics and nerve conduction in workers recently exposed to lead as BLLs increased to above 30 µg/dL.⁹⁸ Early psychiatric effects, manifesting at BLLs of 40 to 70 µg/dL, include increased tiredness at the end of the day, disinterest in leisure time pursuits, falling asleep easily, moodiness, and irritability. The physical examination is usually normal,⁴¹ or hypertension may be present. A bluish-purple gingival lead line (Burton line), representing lead sulfide precipitation in patients with poor dentition, is described rarely. One author described grayish stippling of the retina circumferential to the optic disk,¹⁶⁰ but other authors dispute this finding.¹²²

Effects on reproductive function may also be apparent in this range of exposure. Historically, infertility and stillbirths were common among heavily exposed women lead workers. More recent studies found reduced sperm counts, impaired motility, and abnormal morphology in men who work in the battery industry with BLLs above 40 µg/dL⁵ and increased incidence of menstrual irregularity and spontaneous abortion in lead-exposed women who worked in China⁷⁵ and Mexico.¹⁰ Prematurity is more common in children of pregnancies associated with elevated maternal BLLs.¹¹³

Increased blood pressure is probably the most prevalent adverse health effect observed from lead toxicity in adults. Epidemiologic studies document significant associations between hypertension and body lead burdens. The association is particularly strong for adult men ages 40 to 59 years, with an approximate 1.5 to 3.0 mm Hg increase in systolic pressure for every doubling of BLL beginning at 7 µg/dL.^{126,167} Additional studies correlate body lead burden with several other disorders of aging, including a decline in cognitive ability,^{147,154} essential tremor,⁴³ cardiovascular and cerebrovascular events,^{73,86,108} electrocardiographic abnormalities,³⁰ chronic renal dysfunction,^{86,93} osteoporosis,¹⁵ and cataract prevalence.¹⁴⁵

Organic Lead

Clinical symptoms of TEL toxicity are usually nonspecific initially and include insomnia and emotional instability.^{9,144} Nausea, vomiting, and anorexia may occur. The patient may exhibit tremor and increased deep tendon reflexes. In more severe cases, these symptoms progress to encephalopathy with delusions, hallucinations, and hyperactivity, which may resolve or deteriorate to coma and, occasionally, death. Severely ill patients may also develop liver and kidney injury. Because many reported patients were exposed via intentional abuse of leaded gasoline, much of the literature reporting this syndrome may be confounded by accompanying volatile hydrocarbon toxicity.¹⁶⁴ Of note, in contrast to inorganic lead poisoning, patients with significant TEL toxicity do not consistently manifest hematologic abnormalities or elevations of heme synthesis pathway biomarkers. In addition, significant neurotoxicity may occur at BLLs considerably lower than those typically associated with inorganic lead poisoning.⁶⁷ A case report details the clinical course of a 13 year-old boy who

unintentionally ingested a mouthful of fuel stabilizer containing 80% to 90% TEL. He developed progressive tremor, weakness, hallucinations, myoclonus, and hyperreflexia and required mechanical ventilation for 2 days and prolonged hospitalization for management of persistent hallucinations, weakness, dysphagia, and urinary and fecal incontinence. His BLL peaked on the third day after ingestion at only 62 µg/dL.¹⁸⁰

DIAGNOSTIC TESTING

Clinical Diagnosis in Symptomatic Patients

For all patients in whom plumbism is considered based on clinical manifestations, the medical evaluation should first include a comprehensive medical history. Further inquiry should elicit environmental, occupational, or recreational sources of exposure as detailed earlier (Tables 96–1 and 96–2). Plumbism is more likely in a child between the ages of 1 and 5 years with prior plumbism or noted elevated BLLs; history of pica or acute unintentional ingestions;⁶⁵ aural, nasal, or esophageal foreign bodies;¹⁷⁹ history of iron-deficiency anemia; residence in a pre-1960s–built home, especially with deteriorated paint, or one that has undergone recent remodeling; family history of lead poisoning; or foreign-born status.^{3,32,181} Affected children may manifest persistent vomiting, lethargy, irritability, clumsiness, or loss of recently acquired developmental skills; afebrile seizures; or evidence of child abuse or neglect.^{52,149} In adults, the history should focus on occupational and recreational activities that might involve lead exposure (Table 96–2), a history of plumbism, and gunshot wounds with retained bullets.

The differential diagnosis of plumbism is broad. Adult patients may be misdiagnosed as having carpal tunnel syndrome, Guillain-Barré syndrome, sickle cell crisis, acute appendicitis, renal colic, or infectious encephalitis. Children are often initially considered to have viral gastroenteritis or even to have insidious symptoms passed off as a difficult developmental phase.

A patient who presents to the emergency department with potential lead encephalopathy presents the physician with a dilemma: severe lead toxicity requires urgent diagnosis, but confirmatory blood lead assays are not usually rapidly available.¹²⁰ For adults, a history of occupational exposure is often available from medical records or family members, and lead encephalopathy can be strongly considered with positive supportive laboratory findings such as anemia, basophilic stippling, elevated erythrocyte protoporphyrin (especially >250 µg/dL, sometimes available on an urgent basis), and abnormal urinalysis. In this context, it might be appropriate to institute presumptive chelation therapy while awaiting a BLL. In children, a similar indication for presumptive treatment would be suggested by a constellation of clinical features and ancillary studies, such as age 1 to 5 years, a prodromal illness of several days to weeks duration (suggestive of milder lead-related symptoms), history of pica and source of lead exposure, the laboratory features noted above (which are equally helpful in young children), radiologic findings of dense metaphyseal “lead lines” at wrists or knees (Fig. 96–3), or evidence of recent pica for ingested foreign bodies or lead paint particles on abdominal radiographs (Figs. 96–5 and 96–6). Radiographic confirmation of retained bullets or shrapnel may be relevant in patients of any age (Fig. 96–7).^{50,94,148,153} In both adults and children, the decision to institute empiric chelation treatment should not deter additional emergent diagnostic efforts to exclude or to confirm other important entities while BLLs are pending. An important consideration in this context may be the suspicion of an acute, potentially treatable CNS infection (eg, bacterial meningitis or herpetic encephalitis). Lumbar puncture may be dangerous in patients with severe lead encephalopathy because of the risk of cerebral herniation.³⁵ If immediate lumbar puncture is thought to be essential, a computed tomography scan should be first obtained to determine cerebral edema, midline shift, or other evidence of high risk for herniation. If a lumbar puncture is performed, the minimal amount of fluid necessary for diagnosis (<1 mL) should be removed using a small-gauge needle.

FIGURE 96–6. **(A)** Abdominal radiograph of a child who had massive paint chip ingestion. The dispersed radiodense (white) fragments are noted to follow the outline of the large intestine. **(B)** No remaining lead is seen on follow-up radiograph after whole-bowel irrigation. (Used with permission of Department of Radiology, St. Christopher’s Hospital for Children, Philadelphia, PA.)

FIGURE 96–7. Abdominal radiograph of an 8 year-old child who sustained a shotgun wound to the right paraspinal area, with resultant paraplegia and multiple visceral injuries. The blood lead concentration was found to be 60 $\mu\text{g}/\text{dL}$ at 11 weeks after injury, and chelation therapy was commenced. (Used with permission of Children’s Hospital of Philadelphia, Department of Radiology, Philadelphia, PA.)

Laboratory Evaluation

In patients suspected of having plumbism, laboratory testing is used to augment the evaluation of both lead exposure and lead toxicity. The whole BLL is the principal measure of lead exposure available in clinical practice, reflecting both recent and remote exposure. In any patient suspected of symptomatic plumbism, whole blood should be collected by venipuncture into special lead-free evacuated tubes. The BLL is typically determined by atomic absorption spectrophotometry. For asymptomatic children, BLL screening is often performed by capillary blood testing for convenience; however, venous confirmation of elevated capillary lead concentrations, unless extremely high (eg, $\geq 70 \mu\text{g}/\text{dL}$) or unless the patient is clearly symptomatic, is still considered mandatory before chelation or other significant interventions. Hair and urine lead concentrations have no clinical utility. The erythrocyte protoporphyrin concentration reflects inhibition of the heme synthesis pathway (Chap. 22) and was used as a screening tool in the past, but it is no longer considered sufficiently sensitive. The erythrocyte protoporphyrin concentration test may still be useful for tracking response to therapy and in distinguishing acute from chronic lead poisoning; as an adjunct to the emergency diagnosis of symptomatic plumbism if emergent BLL determination is not available; and, rarely, in the evaluation of suspected factitious plumbism. Routine serum chemistries, kidney function tests, liver function tests, urinalysis, and complete blood count are indicated in patients who are symptomatic or about to undergo chelation therapy. Radiographic studies may reveal retained bullets (Fig. 96–7) or recent lead ingestion. Abdominal radiographs may reveal lead paint chips or other ingested lead foreign material (Figs. 96–5 and 96–6). The finding of “lead lines,” metaphyseal densities at the ends of long bones in young children, may substantiate a clinical diagnosis of plumbism before BLLs are available (Fig. 96–3), although dense metaphyseal bands are rarely caused by other causes, including other metals (arsenic, bismuth, and mercury), healing rickets, and recovery from scurvy.^{130,180}

Finally, two measures of cumulative lead exposure are available. X-ray fluorescence technology measures bone lead, and thus indirectly estimates total body lead burden. The cumulative blood lead index, derived from several BLLs measured over the presumed course of lifetime lead exposure, calculated as an area under the concentration curve, is also described.⁶⁹ Both techniques are used in research studies of issues concerning past chronic lead exposure and a variety of current health outcomes.^{68,85,175}

SCREENING

Although outside the scope of this discussion, screening is an essential public health practice for the prevention of severe plumbism in both children and adults from high-risk settings. Table 96–5 outlines the current CDC^{20,26,27} pediatric recommendations, which also are endorsed by the American Academy of Pediatrics.³ Likewise, the Occupational Safety and Health Administration (OSHA) maintains a lead standard for US workers formulated to reduce workplace exposure to lead, decrease symptomatic lead poisoning, and provide quality medical care to workers with elevated BLLs.^{168–171} Table 96–6A summarizes the OSHA-mandated action BLL values for worker notification, removal, and reinstatement. An expert panel convened by the Association of Occupational and Environmental Clinics published an alternative set of health-based management recommendations for lead exposed workers. The authors propose that their recommendations are more reflective of recent research linking adverse health outcomes to chronic, low-dose lead exposure.⁸⁶ These guidelines are summarized in Table 96–6B.

TABLE 96–5. Pediatric Screening and Follow-up Guidelines^{3,20,24,27}

Screening

1. The AAP and CDC recommend screening all children who are Medicaid eligible at age 1 and 2 years (and those ages 3–6 years who have not been screened previously). Children who may not be Medicaid eligible but whose families participate in any poverty assistance program should also be screened.
2. Certain local health departments (eg, New York, Chicago, and Philadelphia) recommend screening at younger ages or more frequently. Such recommendations include starting at age 6–9 months, testing every 6 months for children younger than 2 years, and provision of additional education and more rapid follow-up testing for children younger than 12 months old whose BLLs are 6–9 µg/dL.
3. In addition, children who are not Medicaid eligible but are designated high-risk by their state or local health departments should be screened as per these local policies.^a
4. For children who are neither Medicaid eligible nor live in areas with locale-specific health department guidelines, recommendations are less clear. The AAP supports universal screening of such children as well.^b
5. Recent immigrants, refugees, or international adoptee children should be screened on arrival to the United States.

Follow-Up

B Pb (µg/dL)	Recommended Action
≤9 ^c	Retest in one year
10–14	Retest in 3 months; education ²⁹
15–19	Retest in 2 months; education; if the BLL is 15–19 µg/dL twice, refer for case management
20–44	Clinical evaluation; education; environmental investigation and lead hazard control
45–69	Clinical evaluation and case management within 48 hours; education; environmental investigation and lead hazard control; chelation therapy ^{1,22}
≥70	Hospitalize child; immediate chelation therapy; education; environmental investigation and lead hazard control

^aMany relevant state and city health department contacts may be located at: <http://www.cdc.gov/nceh/lead/about/program.htm>. ^bThe 1997 CDC guidance²⁸ allowed for targeted screening of some children of low-risk geographic and demographic background based on a personal risk questionnaire. Subsequent studies have found that such survey-based targeted screening is not well validated.¹ Nevertheless, a listing of potential risk factors may be instructive and is summarized here. Screening was recommended if a child had any of the following high-risk factors:

Housing: Lives in or regularly visits a home built before 1950; lives in or regularly visits a home built before 1978 undergoing remodeling or renovation (or renovated within 6 months).

Medical history: Pica for paint chips or dirt; iron deficiency.

Personal, family, and social history: Personal, family, or playmate history of lead poisoning; parental occupational, industrial, hobby exposures; live in proximity to major roadway; use of hot tap water for consumption; use of complementary remedies, cosmetics, ceramic food containers; trips or residence outside United States; parents are migrant farm workers, receive poverty assistance.

¹In 2012, the Advisory Committee for Childhood Lead Poisoning Prevention through the CDC reevaluated the use of the 10 µg/dL threshold concern and made two important changes: (1) replacing the term “threshold” with the 97.5 percentile reference values from NHANES data, to reflect no safe level of lead exposure for the young child, and (2) changing the action number to 5 µg/dL from 10 µg/dL. The formal screening recommendations have not yet been changed, but this is expected shortly.

Educational interventions as per Table 96–7.

Chelation therapy as per Table 96–8.

AAP = American Academy of Pediatrics; BLL = blood lead concentration; BPb = venous blood lead; CDC = Centers for Disease Control and Prevention.

TABLE 96–6A. Occupational Safety and Health Administration General Industry^a Standards for Various Blood Lead Concentrations (BLLs)

<i>Number of Tests</i>	<i>BLL (µg/dL)</i>	<i>Action Required</i>
1	≥40	Notification of worker in writing; medical examination of worker and consultation
3 (average)	≥50	Removal of worker from job with potential lead exposure
1	≥60	Removal of worker from job with potential lead exposure
2	<40	Reinstatement of worker in job with potential lead exposure

^aThe construction industry standard is similar for worker notification (at 40 µg/dL) and reinstatement (<40 µg/dL twice) but requires worker removal for a single value ≥50 µg/dL.

TABLE 96–6B. Health-Based Occupational Surveillance Recommendations^a

<i>BLL (µg/dL)</i>	<i>Recommendation</i>
<10	BLL every month for 3 months and then every 6 months (unless exposure increases); if BLL increases >4 µg/dL, exposure evaluation or reduction effort; exposure evaluation or reduction if BLL 5–9 µg/dL for women who are or may become pregnant
10–19	As for BLL <10 µg/dL and BLL every 3 months; exposure evaluation and reduction effort; consider removal if no improvement with exposure reduction or complicating medical condition ^b ; resume BLL q 6 months if 3 BLLs <10 µg/dL
≥19	Remove from exposure if BLL >30 µg/dL or repeat BLL in 4 weeks; BLL every month; consider return to work after BLL <15 µg/dL twice

^aAll potentially lead-exposed workers warrant preemployment clinical evaluation, baseline blood lead concentration (BLL), and serum creatinine concentration. ^bSuch conditions include chronic kidney disease, hypertension, neurologic disorders, and cognitive dysfunction.

Data from Kosnett MJ, Wedeen RP, Rothenberg SJ, et al: Recommendations for medical management of adult lead exposure. *Environ Health Perspect.* 2007;115:463–471.

MANAGEMENT

There are several caveats about the management of patients with lead poisoning. First, the most important aspect of treatment is removal from further exposure to lead. Unfortunately, effective implementation of this therapy is often beyond the control of the clinician but rather depends on a complex interplay of public health, social, and political actions. Currently, the ability to control exposure is generally more applicable to adults with occupational exposures than to children exposed to residential hazards. Second, in children for whom some residual lead exposure potentially continues, optimization of nutritional status is vital in order to minimize absorption. Finally, pharmacologic therapy with chelators, although a mainstay of therapy for symptomatic patients, is an inexact science, with numerous unanswered questions despite almost 50 years of clinical use.^{2,4,85} The rationale for chelation therapy of lead poisoned patients is that chelators complex with lead, forming a chelate that is excreted in urine, feces, or both. Chelation therapy increases lead excretion, reduces blood concentrations, and reverses hematologic markers of toxicity during therapy. Reports from the 1950s found symptomatic improvement in adults chelated for lead colic.¹⁷⁴ The institution of effective combination chelation treatment of childhood lead encephalopathy in the 1960s contributed to the dramatic decline in mortality and morbidity of that

devastating degree of plumbism.³⁴ However, the same era saw major advances in pediatric critical care in general and medical management of increased ICP in particular. The situation of chelation therapy for asymptomatic patients with mildly to moderately increased body burdens of lead is even less clear, and many questions regarding efficacy and safety remain.^{32,60,85,124} To date, long-term reduction of target tissue lead content or reversal of toxicity is not demonstrated in human trials.^{42,102,138}

Decreasing Exposure

All patients with significantly elevated BLLs warrant identification of the lead exposure source, and specific environmental and medical interventions, or both (Table 96–7). In adults, this usually involves worksite changes.^{41,86,144} The risk of occupational lead exposure correlates with several factors that contribute to the occurrence of respirable lead fumes or dust particles in the worksite atmosphere.¹⁴⁴ First, there are hazards inherent in the work process itself, including high temperatures; significant aerosol, dust, or fume production; and a less mechanized workplace (with resulting greater “hands-on” employee exposure). Second, the adequacy of dust elimination, such as local and general ventilation, is critical. The third category is that of worksite and personal hygiene, including proper use of protective clothes and equipment, and thorough housekeeping. Remedial actions might include improvements in ventilation, modification of personal hygiene habits, and optimal use of respiratory apparatus. It is vital to prohibit smoking, eating, and drinking in a lead exposed work area. Work clothes should be changed after each shift and should not be lockered together with street clothes.

TABLE 96–7. Evaluation and Management of Patients with Lead Exposure

Workplace Efforts

Adults

- Implement careful lead exposure monitoring (Table 96–6B)
- Improve ventilation
- Use a respiratory protective apparatus
- Wear protective clothing; change from work clothes before leaving worksite
- Modify personal hygiene habits
- Prohibit eating, drinking, and smoking at the worksite
- Evaluate possible sources beyond occupational setting (Tables 96–1 and 96–2)

Children

- Notify the local health department to initiate home inspection and abatement as needed
- Home lead paint abatement (professional contractors if possible; use plastic sheeting, low dust-generating paint removal; replacement of lead-painted windows, floor treatment; final cleanup with high-efficiency particle air vacuum, wet mopping)
- Avoid most hazardous areas of the home and yard
- Dust control: Wet mopping, sponging with high-phosphate detergent; frequent hand, toy, and pacifier washing
- Soil lead exposure reduction by planting grass and shrubs around the house
- Use only cold, flushed tap water for consumption
- Optimize nutrition to reduce lead absorption: avoid fasting; give an iron, calcium, vitamin C sufficient diet; supplement iron and calcium as necessary
- Avoid food storage in open cans
- Avoid imported ceramic containers for food and beverage use

Evaluate parental occupations and hobbies and eliminate high-risk activity

Consider possible sources beyond lead paint exposure (Tables 96–1 and 96–2)

In patients with plumbism caused by retained bullets, surgical removal of this lead source should be considered.^{28,94,107} Table 96–7 also summarizes several specific educational guidelines that may be offered to parents of lead-exposed children.^{3,14,22} Overarching principles include home lead paint abatement (done preferably by professionals, with the family out of the home), home dust reduction techniques, decreasing soil lead exposure, and nutritional evaluation and counseling. Patients manifesting iron deficiency should be treated, and for others, a diet sufficient in trace nutrients, particularly iron and calcium (which may decrease lead absorption) and vitamin C (which may enhance renal lead excretion) is likely of value.³ Clinicians who have primary responsibility for children with elevated BLLs should refer to the exhaustive monograph developed by the CDC, which details such pediatric case management.²²

Occasionally, children may require urgent GI decontamination to reduce ongoing acute lead exposure. Patients with large burdens of lead paint chips may benefit from prompt institution of whole-bowel irrigation (WBI) (Fig. 96–6) (Antidotes in Depth: A2). The presence of ingested lead foreign bodies is a unique situation that requires careful individualization of management. Several case reports document rapid absorption, with significantly elevated BLLs measured within 24 hours of ingestion in some cases. Such patients warrant baseline BLL determination and frequent repeat BLLs, with consideration for prompt endoscopic removal, particularly with gastric location and increasing BLLs.^{106,112,172} Proton pump inhibitor and prokinetic therapy are recommended for gastric foreign bodies in an effort to decrease gastric acidity, retention time, and resultant lead dissolution.⁵¹ WBI may be an adjunct for more distally located foreign bodies but has not been uniformly successful. Endoscopic or surgical removal may be indicated with delayed passage of foreign bodies, inability to tolerate WBI due to intestinal obstruction, or rapid elevations in BLL soon after foreign body ingestion.^{51,112,172} The issue of concomitant chelation therapy in patients with significant GI lead burdens is addressed in the following section.

Chelation Therapy

The indications for and specifics of chelation therapy are determined by the age of the patient, the BLL, and clinical symptomatology (Table 96–8). Three chelators are currently recommended as drugs of choice for the treatment of lead poisoning: BAL (Antidotes in Depth: A25) and CaNa₂EDTA (Antidotes in Depth: A27) are used parenterally for more severe cases, and succimer (Antidotes in Depth: A26) is available for oral therapy. A fourth drug, D-penicillamine, has been used orally for patients with mild to moderate excess lead burdens. Unfortunately, D-penicillamine has a toxicity profile that includes life-threatening hematologic disorders and reversible, but serious, dermatologic and kidney effects; consequently, since 1991, its role in lead poisoning treatment at most centers has been largely replaced by succimer. Currently, the American Academy of Pediatrics recommends D-penicillamine use only when unacceptable adverse reactions to both succimer and CaNa₂EDTA occur, and it remains important to continue chelation.^{2,3}

TABLE 96–8. Chelation Therapy Guidelines^{2,3,22,82,125,128} for Initial Course of Treatment^a

Condition, BLL (µg/dL)	Dose	Regimen/Comments
Adults		
Encephalopathy	BAL 450 mg/m ² /d ^a and CaNa ₂ EDTA 1000–1500 mg/m ² /d ^a	75 mg/m ² IM every 4 hours for 5 days Continuous infusion or two to four divided IV doses for 5 days (start 4 hours after BAL)
Symptoms suggestive of encephalopathy or >100	BAL 300–450 mg/m ² /d ^a and CaNa ₂ EDTA 1500 mg/m ² /d ^a	50–75 mg/m ² IM every 4 hours for 3–5 days (base dose, duration on BLL, severity of symptoms; see text) Continuous infusion or two to four divided IV doses for 5 days (start 4 hours after BAL) Lab: Baseline CT scan; CBC, Ca ²⁺ , BLL, BUN, Cr, LFTs, U/A; repeat CBC, Ca ²⁺ , BUN, Cr, LFTs, U/A daily; BLL on days 3 and 5
Mild symptoms or 70–100	Succimer 700–1050 mg/m ² /d	350 mg/m ² tid for 5 days, then bid for 14 days. Remove from exposure (Table 96–7) Lab: CBC, BLL, BUN, Cr, LFTs, U/A; repeat CBC, LFTs, BLL on days 7 and 21
Asymptomatic and <70	Usually not indicated	—
Children		
Encephalopathy	BAL 450 mg/m ² /d ^a and CaNa ₂ EDTA 1500 mg/m ² /d ^a	75 mg/m ² IM every 4 hours for 5 days Continuous infusion or two to four divided IV doses for 5 days (start 4 hours after BAL) Lab: Baseline AXR, CT scan, CBC, Ca ²⁺ , Na ⁺ , BEL, BUN, Cr, LFTs, U/A; repeat CBC, Ca ²⁺ , Na ⁺ , BUN, Cr, LFTs, U/A daily; BLL on days 3 and 5
Symptomatic (without encephalopathy) or >49	BAL 300–450 mg/m ² /d ^a and CaNa ₂ EDTA 1000–1500 mg/m ² /d ^a	50–75 mg/m ² IM every 4 hours for 3–5 days (base dose, duration on BLL, severity of symptoms; see text) Continuous infusion or two to four divided IV doses for 5 days (start 4 hours after BAL) Lab: Baseline AXR, CBC, Ca ²⁺ , BLL, BUN, Cr, LFTs, U/A; repeat CBC, Ca ²⁺ , BUN, Cr, LFTs, U/A on days 3 and 5 and BLL day 5
Asymptomatic: 45–49	Succimer 700–1050 mg/m ² /d ^a or CaNa ₂ EDTA, 1000 mg/m ² /d ^a	350 mg/m ² tid for 5 days and then bid for 14 days Lab: Baseline AXR, CBC, BLL, LFTs; repeat CBC, LFTs, BLL days 7 and 21 Continuous infusion or two to four divided IV doses for 5 days (see text) Lab: Baseline AXR, CBC, Ca ²⁺ , BLL, BUN, Cr, LFTs, U/A; repeat Ca, BUN, Cr, LFTs, U/A on days 3 and 5 and BLL on day 5
20–44	Routine chelation not indicated (see text) Attempt exposure reduction	If succimer used, same regimen as per above group (Table 96–7)
<20	Chelation not indicated Attempt exposure reduction	(Table 96–7)

Subsequent treatment regimens should be based on postchelation BPs and clinical symptoms (see text).

Approximate equivalent doses are expressed in mg/kg: BAL 450 mg/m²/d (–24 mg/kg/d); 300 mg/m²/d (–16 mg/kg/d).

CaNa₂EDTA 1000 mg/m²/d (–25–50 mg/kg/d); 1500 mg/m²/d (–30–75 mg/kg/d); adult maximum dose 3–3 g/d; succimer 150 mg/m² (–10 mg/kg).

^aSome clinicians recommend CaNa₂EDTA alone in these contexts (see text).

AXR = abdominal radiography; BEL = blood lead concentration; BPs = venous blood lead; BUN = blood urea nitrogen; Ca = calcium; CaNa₂EDTA = edetate calcium disodium; CBC = complete blood count; Cr = creatinine; CT scan = computed tomography scan of the brain; IM = intramuscular; IV = intravenous; Lab = supported laboratory and radiologic evaluation; LFTs = hepatic aminotransferases; U/A = urinalysis with microscopy (frequent monitoring of urine depicts analysis for hematuria and proteinuria also advised during CaNa₂EDTA therapy).

Chelation is not a panacea for lead poisoning. It is a relatively inefficient process, with a typical course of therapy decreasing body content of metal by only 1% to 2%.^{85,111} Furthermore, there is little evidence that chelators have significant access to critical sites in target organs, particularly in the brain.³⁷ Assumptions that reducing BLL will improve subtle neurocognitive dysfunction or other subclinical organ toxicity are appealing theoretically but unproven.^{42,138}

Children

Lead encephalopathy is an acute life-threatening emergency and should be treated under the guidance of a multidisciplinary team in the intensive care unit of a hospital experienced in the management of critically ill children. Encephalopathy requires treatment by combination parenteral chelation therapy with maximum-dose BAL and CaNa₂EDTA along with meticulous supportive care.^{2,22,34} Such combination therapy has a dramatic effect on decreasing BLL—to 50% or less of baseline within 15 hours and to 75% to 80% of baseline by 48 to 72 hours. It is far superior to monotherapy with CaNa₂EDTA in this regard.³⁴

Chelation is instituted with 450 mg/m²/d (or 25 mg/kg/d) of intramuscular (IM) BAL in six divided doses.^{2,22} The second dose of BAL is given 4 hours later followed immediately by IV CaNa₂EDTA, in maximum concentration of 0.5%

solution, at 1500 mg/m²/d (or 50 mg/kg/d) as a continuous infusion or in divided-dose infusions over several hours.^{2,22,125} The delay in initiating CaNa₂EDTA infusion is based on past observations of clinical deterioration in encephalopathic patients treated with CaNa₂EDTA alone.^{2,34} Therapy is typically continued with both agents for 5 days, although in milder cases with prompt resolution of encephalopathy and decrease of BLL to below 50 µg/dL, BAL may be discontinued after 3 days, with continuation of CaNa₂EDTA alone for 2 more days.

The presence of radiopaque material in the GI tract on radiography has raised concern that parenteral chelation might enhance absorption of residual gut lead. This issue is not settled fully,^{32,78} but most experts advocate initiation of parenteral chelation without delay in seriously symptomatic patients. It seems reasonable to simultaneously attempt whole bowel irrigation with a polyethylene glycol preparation.² One case report described the successful use of chelation therapy begun with parenteral BAL and CaNa₂EDTA and then enteral succimer (initiated after 3 days of WBI) for a child with lead encephalopathy and an extraordinarily high BLL of 550 µg/dL.⁵⁷ This issue applies as well to ingested lead foreign bodies, as noted above.^{106,112,172} Generally, oral fluids, feedings, and medications are withheld for at least the first several days. Careful provision of adequate IV fluids optimizes kidney function while avoiding overhydration and the risk of exacerbating cerebral edema. The occurrence of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) may be associated with lead encephalopathy,^{34,163} so urine volume, specific gravity, and serum electrolytes should be closely monitored, especially as fluids are gradually liberalized with clinical improvement (Chap. 19). In the context of lead encephalopathy, this approach would need to be tempered by the requirement for maintaining good urine output to optimize chelation efficacy.

Seizure control is usually accomplished with benzodiazepines. Ongoing anticonvulsant therapy is typically continued with phenytoin or phenobarbital. Rarely, continuous infusions of midazolam or high-dose pentobarbital therapy may be necessary.¹⁷⁸

Modern approaches to the management of cerebral edema and increased ICP have not been critically evaluated in the context of lead encephalopathy. Lumbar puncture should probably be avoided if lead encephalopathy is highly suspected and acute infectious processes are not. Of note, repeated lumbar puncture was used as an adjunct to the treatment of lead encephalopathy associated with increased ICP in the 1950s but was complicated by proximate death when signs of impending herniation were present.³⁵ It seems reasonable that measures such as prevention of hypoxia and hypercarbia with tracheal intubation and controlled ventilation, seizure treatment and prophylaxis, maintenance of adequate cerebral perfusion pressure, mild hyperventilation with PCO₂ of 30 to 35 mm Hg, and neutral head positioning with elevation of the head of the bed to 30 degrees might have a salutary effect at minimal risk of increased iatrogenic morbidity.^{2,162} Mannitol administration may prove beneficial in deteriorating patients and has been particularly suggested as an adjunctive therapy when cerebral edema is complicated by SIADH or impaired kidney function.³⁴ Whether more aggressive measures, such as acute hyperventilation for impending herniation, ICP monitoring, drainage of ventricular cerebrospinal fluid, decompressive craniectomy, induced hypothermia, or barbiturate coma would decrease mortality or morbidity further is unknown.

For children with milder effects or who are asymptomatic with BLL greater than 70 µg/dL, chelation with a two-drug regimen similar to that used for encephalopathy is recommended. It is likely that this group of patients will require only 2 to 3 days of BAL in addition to 5 days of CaNa₂ EDTA. Some authors have suggested that asymptomatic patients in this group, particularly those with BLLs below 100 µg/dL, might also be adequately treated with CaNa₂ EDTA alone,¹⁸¹ succimer plus CaNa₂ EDTA, or even succimer alone, most recently a large cohort of 1193 Nigerian children with moderate to severe lead poisoning were managed with succimer alone. Although data concerning long term efficacy is still emerging, this appears to be a safe alternative if circumstances preclude standard two drug chelation.^{164a} Intensive care monitoring may be prudent for such patients as well, at least during the initiation of chelation therapy.¹¹¹

Chelation therapy is widely recommended for asymptomatic children with BLLs between 45 and 70 µg/dL.^{2,4,22,111} Children without overt symptoms may be treated with succimer alone, which has documented efficacy in lowering BLLs and short-term safety since its approval by the Food and Drug Administration in 1991.^{63,91} Succimer is initiated at 30 mg/kg/d (or 1050 mg/m²/d) orally in three divided doses; this is continued for 5 days and then decreased to 20 mg/kg/d (or 700 mg/m²/d) in two divided doses for 14 additional days.^{2,62} The original data establishing this empiric dosing regimen were based on body surface area rather than weight.⁶² For younger children, the alternative dosing by body weight results in suboptimal dosing.¹³⁶ Although the ability to chelate children orally with succimer makes it tempting to prescribe routinely for outpatient therapy and some animal evidence suggests succimer does not enhance enteral lead absorption,⁸⁰ clinical reports suggest that children must be protected from continued lead exposure during succimer chelation.^{31,33} Home abatement and reinspection should be accomplished before initiation of ambulatory succimer therapy; if this is not feasible, hospitalization is still warranted. Alternative regimens (for rare patients with succimer intolerance or allergy or because of parental noncompliance) include parenteral chelation with CaNa₂EDTA at 25 mg/kg/d for 5 days.²

After initial chelation therapy, decisions to repeat treatment are based on clinical symptoms and follow-up BLLs. Patients with encephalopathy or any severe symptoms or with an initial BLL above 100 µg/dL often require repeated courses of treatment. It is suggested that at least 2 days elapse before restarting chelation. The precise regimen and dosing of chelating agents are determined by ongoing symptomatology and the repeat BLLs (Table 96–8). A third course of chelation should rarely be necessary sooner than 5 to 7 days after the second course ends.¹²⁵ For patients with milder degrees of plumbism (eg, asymptomatic, initial BLL <70 µg/dL), it is reasonable to allow 10 to 14 days of reequilibration before restarting treatment.²

The management of asymptomatic children with BLLs of 20 to 44 µg/dL is controversial.^{31,100,110,166} The National Institutes of Health–sponsored Treatment of Lead-exposed Children (TLC) trial found only modest efficacy of succimer in reducing BLL. Furthermore, at 3 years postenrollment, no benefit was noted in treated patients on measures of cognition, neuropsychiatric function, or behavior.¹³⁸ This large study enrolled 780 children in a multicenter, randomized, placebo-controlled, double-blind trial, but it still has been criticized, particularly for using a single chelator and having failed to lower BLL significantly over time between treated and control groups.¹⁵¹ Of note, small but statistically significant decrements in growth velocity were noted in the treatment group, which might reflect trace mineral depletion.¹²⁴ Since its initial publication, the primary findings of the TLC trial on lack of cognitive improvement were confirmed in a 7 year follow-up study.⁴² In addition, a reanalysis of the original data found that decreasing blood concentrations did correlate with improved cognitive scores over the initial 36 month trial period (~4 IQ points for each 10 µg/dL decrease in BLL), but only in the placebo group.⁹⁶ Nevertheless, there may still be potential indications for occasional chelation treatment in this group, including BLLs at the higher end of the range (eg, 35–44 µg/dL), especially if BLLs remain the same or increase over several months after rigorous environmental controls are instituted, in younger children (eg, younger than 2 years), in children with evidence of biochemical toxicity (an elevated erythrocyte protoporphyrin concentration, after iron supplementation, if necessary), or any hint of subtle symptoms. Currently, the CDC¹⁹ and the American Academy of Pediatrics^{2,3} recommend aggressive environmental and nutritional interventions with close monitoring of blood lead concentrations, without routine chelation therapy, for such children.

BLLs of 5 to 19 µg/dL are defined by the CDC as representing excessive exposure to lead but not requiring chelation therapy. Close monitoring (for the 5–14 µg/dL range) and careful environmental investigation and interventions as necessary (particularly for the 15–19 µg/dL range) are appropriate and sufficient.^{2,3,22} The educational approaches outlined earlier should be included in the case management of all children with even modestly elevated lead levels (Table 96–7).

Adults

General Considerations. The first principle in the treatment of adults with lead poisoning is that chelation therapy may not substitute for adherence to OSHA lead standards at the worksite and should never be given prophylactically.^{41,82} In addition to the guidelines for decreasing lead exposure noted earlier, chelation therapy is indicated for adults with significant symptoms (encephalopathy, abdominal colic, severe arthralgias, or myalgias), evidence of target organ damage (neuropathy or nephropathy), and possibly in asymptomatic workers with markedly elevated BLLs or evidence of biochemical toxicity.^{86,134,144,150} Table 96–8 outlines suggested chelation therapy regimens for adults. For encephalopathic adult patients, our practice is to recommend combined BAL and CaNa₂EDTA therapy, just as for children, although some clinicians suggest that adults with severe lead poisoning may be successfully treated with CaNa₂EDTA alone in doses of 2 to 4 g/d by continuous IV infusion.⁸⁴ Recent reports support the use of succimer in adult patients with mild to moderate plumbism after environmental and occupational remedies have been instituted.^{92,128} Chelation therapy should also be considered in the perioperative period for patients undergoing surgical removal of retained bullets or débridement of adjacent lead-contaminated tissue.^{94,107,148} Treatment of patients with acute TEL toxicity is largely supportive, with sedation as necessary. For patients seen soon after a large-volume ingestion, nasogastric suction, with airway protection as needed, may be warranted. In general, chelation therapy for TEL toxicity is associated with enhanced lead excretion¹² but has not been found to be clinically efficacious.^{144,164,180} However, for symptomatic, especially encephalopathic patients with very elevated BLLs (in whom there may be a significant component of metabolically derived inorganic lead toxicity), we recommend chelation therapy.

Pregnancy, Neonatal, and Lactation Issues. An area of particular concern in the management of adult plumbism involves decisions regarding therapy during pregnancy. As noted previously, lead freely passes the placental barrier and accumulates in the fetus throughout gestation. Chelation therapy during early pregnancy poses theoretical problems of teratogenicity, particularly that caused by enhanced excretion of potentially vital trace elements, or translocation of lead from mother to fetus (Antidotes in Depth: A25, A26, and A27). Symptomatic pregnant women with elevated BLLs certainly warrant chelation therapy, regardless of these concerns. Additionally, of some reassurance regarding fetal health, a case series and 25 year literature review of lead poisoning during pregnancy found no reports of chelation-associated birth defects in the handful of published cases.¹⁵² It should be noted that despite decreases in maternal BLL with chelation therapy, newborn BLLs may be considerably higher and, in some cases, may approximate the pretreatment maternal BLL,

implying limited efficacy for in utero fetal chelation. However, in these cases, the hemoglobin concentration of the newborn was generally much higher than that of the mother, and thus some of the maternal–neonatal difference in BLL may simply reflect this difference in hemoglobin concentration and hence total blood lead content. In general, there currently seems little support for routine chelation therapy in pregnant women who would not otherwise warrant treatment based on their own symptoms or degree of elevated BLL. Calcium carbonate supplementation may be considered because its use is associated with decreased bone resorption during pregnancy and thus possibly lessened fetal lead exposure.⁷⁴

Postnatally, infant BLLs may decline over time without chelation, but this occurs very slowly.¹⁴¹ In two reported neonates exposed to prenatal maternal chelation who were then monitored for 2 weeks postpartum, the BLL remained stable or increased until chelation therapy was instituted.^{123,165} In two additional cases of neonates whose mothers were not treated prepartum, BLLs also remained stable or increased for 17 days to 3 weeks.^{55,159} Thus, postpartum chelation therapy is warranted for neonates, depending on BLLs, as per the guidelines described above for older children. Exchange transfusion might be considered for neonates with extremely elevated BLLs.¹³ Succimer chelation therapy was used for one neonate with presumed organic lead exposure via maternal gasoline sniffing.¹²⁹

Lastly, the issue of allowing mothers with elevated BLLs to breastfeed their infants may arise. Breast milk from heavily exposed mothers may be a potential source of lead exposure and may require lead concentration analysis before breastfeeding can be safely recommended.^{7,48} One small case series found that breast milk from two women with BLLs of 34 and 29 µg/dL, respectively, had clinically insignificant lead content (<0.01 µg/mL).⁷ Breast milk analysis may be warranted in some cases, particularly with BLLs of 35 µg/dL or greater, before safely advising continued nursing. Despite these considerations, the majority of women without excessive lead exposure should still be encouraged to breastfeed. Of note, one study has found that a relatively simple intervention, calcium supplementation (1200 mg/d of elemental calcium as calcium carbonate), reduces breast milk lead content by 5% to 10%.⁴⁷

SUMMARY

- Lead is a widely distributed element that has long been used by humans for a variety of purposes, including waterproofing; electrical and radiation shielding; and the production of ammunitions, paints, plastics, ceramics, glass, and explosives.
- Lead poisoning, or plumbism, has an equally long history, but today it is primarily manifest in young children exposed to deteriorated lead paint and as an occupational toxic exposure for adult workers.
- Lead causes multiorgan toxicity, affecting especially the hematologic and neurologic systems in patients of all ages and causing hypertension in adults. This may result in a broad spectrum of clinical effects ranging from subtle neurocognitive effects to vague constitutional symptoms to acute encephalopathy, intracranial hypertension, cerebral edema, and death.
- The mainstays of treatment are removal from exposure. Chelation therapy is reserved for patients with symptoms or significantly elevated body lead burdens. Defining a group of asymptomatic patients that will benefit from chelation therapy has been difficult and controversial.
- Parenteral chelation with CaNa₂EDTA and BAL is efficacious in lowering BLLs and reducing mortality and morbidity from severe lead poisoning. Succimer, an oral chelator, also has efficacy in reducing BLLs in asymptomatic children, although the neurocognitive benefit of doing so is unproven.

A26 ANTIDOTES IN DEPTH

Succimer (2,3-Dimercaptosuccinic Acid)

Mary Ann Howland

INTRODUCTION

Succimer (meso-2,3-dimercaptosuccinic acid, DMSA) is an orally active metal chelator that is approved by the US Food and Drug Administration (FDA) for the treatment of lead poisoning in children with blood lead concentrations higher than 45 $\mu\text{g/dL}$. Succimer is also used to treat patients poisoned with arsenic and organic and inorganic mercury. Succimer has a wider therapeutic index and exhibits many advantages over dimercaprol and edetate calcium disodium (CaNa_2EDTA), the two other chelators used for the same clinical problems. Animal studies suggest that succimer does not redistribute lead or arsenic to the central nervous system. The role of succimer alone and in conjunction with other chelators to treat lead encephalopathy continues to be defined.^{60,73}

HISTORY

Succimer was initially synthesized in 1949 in England.⁷¹ In 1954, antimony-a,a'-dimercaptopotassium succinate (TWSb) was developed to treat schistosomiasis.⁴² TWSb is antimony bound to the potassium salt of succimer in a 2:3 ratio, forming a water-soluble xenobiotic with 50 times less toxicity than the previously used antimony compound, tartar emetic. Several years later, a group from Shanghai demonstrated the ability of the sodium salt of succimer to increase the LD_{50} of tartar emetic 16-fold in mice.¹⁰⁹ An early review of the Chinese experience with intravenous (IV) succimer in the treatment of occupational lead and mercury poisoning suggested efficacy similar to IV CaNa_2EDTA in increasing urinary lead and to intramuscular (IM) DMPS (racemic-2,3-dimercapto-1-propanesulfonic acid, unithiol) for mercury, with little observed toxicity.¹⁰⁵ This experience, the subsequent widespread use in Asia^{75,78,90,105,106,112} and Europe,^{17,34,40,43,63,99} and the realization that succimer could be used orally,^{7,49} led to US-based animal experiments, human trials, and FDA approval in 1991 for the treatment of lead-poisoned children.

PHARMACOLOGY

Chemistry

Succimer is a white crystalline powder with a molecular weight of 182 Da and a characteristic sulfur odor and taste.⁶ Succimer is the meso form of 2,3-dimercaptosuccinic acid. It is highly polar and water soluble.

Related Agents

DMPS (racemic-2,3-dimercapto-1-propanesulfonic acid, Na salt) is a chelator that, like succimer, is a water-soluble analog of British anti-Lewisite (BAL).^{7,9,23} A dose of 15 mg/kg of DMPS is equimolar to 12 mg/kg of succimer. DMPS has been used in the Soviet Union since the late 1950s and continues to be used in Russia and other former Soviet countries. DMPS, which is an investigational drug in the United States, is marketed in both oral and parenteral forms in Germany as Dimaval. DMPS seems promising in mercury and arsenic poisoning.^{3,5,7,9,11,14,23,45} DMPS is associated with an increase in the urinary excretion of copper and the development of Stevens-Johnson syndrome.^{26,104} Like succimer, DMPS does not appear to redistribute mercury or lead to the brain. Additional research is needed to determine whether DMPS is more advantageous than succimer, given its lower LD₅₀ in mice (5.22 mmol/kg versus 13.58 mmol/kg for succimer) when administered intraperitoneally.

Mechanisms of Action

Succimer contains four ionizable hydrogen ions, giving it four different pK_as—2.31, 3.69, 9.68, and 11.14—with the dissociation of the two lower values representing the carboxyl groups and the two higher values the sulfur groups.⁴ Lead and cadmium bind to the adjoining sulfur and oxygen atoms, whereas arsenic and mercury bind to the two sulfur moieties, forming pH-dependent water-soluble complexes (Fig. A26–1).⁸⁵

FIGURE A26–1. The chelation of cadmium, lead, and mercury with succimer.

Pharmacokinetics and Pharmacodynamics

Succimer is highly protein bound to albumin through a disulfide bond. Subhuman primate studies of IV and oral ²²C succimer indicate that following an IV dose, radiolabelled succimer is eliminated almost exclusively via the kidney, with only trace amounts (< 1%) excreted via feces or expired air.⁷¹ Following the administration of a single oral dose of 10 mg/kg, succimer is rapidly and extensively metabolized.⁶⁸ Approximately 20% of the administered oral dose is recovered in the urine, presumably reflecting the low bioavailability of the drug.¹⁰ Of the total drug eliminated in the urine (20%), 89% is altered and in the form of disulfides of L-cysteine. The majority of the altered succimer is in the form of a mixed disulfide with two molecules of L-cysteine to one molecule of succimer.⁸ The remaining 11% is excreted as unaltered free succimer.⁶⁸ Maximal excretion of succimer occurs in urine specimens collected between 2 and 4 hours after administration. Surprisingly, the blood only contains albumin-bound succimer and no evidence of the altered disulfide moieties, which suggests that the kidney may be involved in the biotransformation of succimer. It is likely that succimer gains entry to the kidney via an active organic anion transporter.^{21,111}

The pharmacokinetics of a single oral dose of succimer were determined in three children and three adults with lead poisoning and in five healthy adult volunteers.³³ Children received 350 mg/m² of succimer and adults received 10 mg/kg of succimer. The peak concentration and the time to peak blood concentration of total succimer (parent vs. altered oxidized metabolites) were similar for all three groups. The half-life of total succimer was 1.5 times longer in the children than in either adult group. The renal clearance of total succimer was greater in healthy adults (CrCl 77 mL/min) than in lead-poisoned adults (CrCl 25 mL/min) and children (CrCl 17 mL/min) with reduced creatinine clearances. Distribution of succimer (parent and/or oxidized metabolites) into erythrocytes appeared greater in poisoned patients than in the healthy adults.³³

The metabolism of succimer was studied in lead-poisoned children and in normal adults.¹⁵ The results indicate that succimer undergoes an enterohepatic circulation facilitated by gastrointestinal (GI) microflora. Similar to the previous pharmacokinetic study, moderate lead exposure impaired the renal elimination of succimer.

ROLE FOR LEAD EXPOSURE

In addition to precise analysis of metal elimination kinetics, measures of clinical outcome are essential for an understanding of the utility of this chelator. The Treatment of Lead-Exposed Children (TLC) trial was a step in that direction.¹⁰² The TLC

trial was a randomized, multicenter, double-blind, placebo-controlled study to examine the effects of succimer on cognitive development, behavior, stature, and blood pressure in children 1 to 3 years of age with blood lead concentrations between 20 and 44 $\mu\text{g/dL}$ and 780 children were enrolled.⁸⁶ The children received up to three courses of 26 days each of succimer compared to placebo. For the first 7 days the children received 350 mg/m^2 three times a day and for the remaining 19 days they received 350 mg/m^2 twice a day. The largest drop in blood lead occurred within the first week of therapy with succimer and then rebounded somewhat. This pattern was repeated with repeated courses. However, at the end of one year, no difference was seen in the blood lead concentrations between the succimer and the placebo groups. There was also no difference in test scores on cognition, behavior, or neuropsychological function.⁸⁶ A follow-up study conducted on those children at age 7 confirmed the lack of benefit in chelating children with succimer whose blood lead concentrations were 20 to 44 $\mu\text{g/dL}$, at ages 1 to 3 years.³⁵ A case study showed similar results. Similarly, succimer showed no benefit on growth in children aged 12 to 33 months with blood lead concentrations of 20 to 44 $\mu\text{g/dL}$.⁸²

Several groups are studying the efficacy of succimer in reducing blood, brain, and tissue lead by using rat and nonhuman primate models of childhood and adult lead poisoning.^{91,92,94} Although monkeys most closely resemble humans in their lead-associated toxicity, using them in studies is costly⁷⁷; the rat model is economical but limited because of species differences in lead and succimer metabolism and efficacy.

The validity of using blood lead concentrations as a marker of brain lead was studied in the adult rhesus monkey. Lead was administered orally for 5 weeks to achieve a target blood lead concentration of 35 to 40 $\mu\text{g/dL}$.³² Five days after the cessation of lead exposure, succimer chelation was initiated in the currently approved dosage regimen. Two IV doses of radioactive lead tracer were administered prior to succimer chelation to study the kinetics of recent versus chronic lead uptake and distribution. Four areas of the brain, as well as blood and bone, were assayed for lead. Merely stopping further lead exposure significantly reduced blood lead concentrations by 63% and brain lead concentrations by 34% compared with pretreatment concentrations, a finding that was not statistically different from succimer administration after halting exposure. However, when an integrated area under the serum lead concentration versus time curve (AUC) blood analysis was used over the 19-day succimer treatment course, instead of a single blood lead concentration, the differences between succimer and control were statistically significant. The clinical significance of these differences is unclear. Succimer-treated animals showed the greatest drop in blood lead concentrations over the first 5 days, while a similar end point was gradually achieved in the control. The lead from both the recent exposure (radioactive tracer lead) and chronic exposure declined to the same extent, independent of treatment with succimer. A better correlation was found between brain prefrontal cortex lead concentrations and an integrated blood lead analysis than with a single blood lead measurement.

Similarly, a study in neonatal rats demonstrated that increasing the duration of succimer chelation from 7 to 21 days decreased brain lead concentrations without a corresponding decrease in blood lead concentrations.⁹¹ The authors proposed that a slow rate of egress of brain lead to the blood was responsible for the demonstrable benefit of prolonging therapy to 21 days. In this study, succimer decreased blood lead concentration by approximately 50% when compared with the vehicle as the control, and this difference persisted for the 21 days of treatment. With succimer treatment, brain lead concentration decreased by 38% at 7 days and by 68% at 21 days. This same group also demonstrated that rats exposed to lead from postnatal days 1 to 30, then treated with succimer, demonstrated reductions in blood and brain lead concentrations and an improvement in cognitive deficits.⁹⁵ Previous animal studies demonstrated the ability of succimer to enhance urinary lead elimination^{41,49,94} and to reduce blood,^{16,30,38,39,54,80,92,94,96,98} brain,^{16,30,80,97,98} liver,⁹⁴ and kidney lead concentrations,^{16,30,38,54,80,98} while either reducing^{16,54,80,98} or demonstrating no effect on bone lead concentrations.^{30,94} These studies differ in the amounts and duration of lead administration prior to chelation, as well as in route, dose, and duration of chelation; however, several months after a course of succimer chelation, tissue lead concentrations had returned to concentrations found in the pretreatment stage.³⁰ Given the limited absolute amount of lead that is actually eliminated by chelation in comparison to the total body burden, particularly bone, these transient effects are not surprising.

Under a variety of experimental conditions in animals, succimer prevents the deleterious effect of lead on heme synthesis,^{16,49,80} blood pressure,⁵⁸ and behavior.⁹⁶

The use of succimer in both children and adults with chronic lead poisoning demonstrated consistent findings.^{18,27,50-52,64,76} During the first 5 days of succimer chelation (1050 $\text{mg/m}^2/\text{d}$ in children, 30 mg/kg/d in adults both in three divided doses), the blood lead concentration dropped precipitously by approximately 60% to 70%. This blood lead concentration remained unchanged during the next 14 to 23 days of continued therapy. Increases in urinary lead excretion are concurrent with the drop in blood lead concentration, with maximal excretion occurring on day 1.^{27,51} Urinary lead excretion exceeds estimated blood content which suggests that some lead is being removed from soft tissues as a concentration gradient is established from tissue to blood to urine.^{27,52} Typically, 2 weeks after the completion of succimer, blood lead concentration rebounds to values 20% to 40% lower than pretreatment values. In the one randomized, double-blind, placebo-controlled trial of succimer use in children with pretreatment blood lead concentrations of 30 to 45 $\mu\text{g/dL}$, follow-up at 1 month and at 6 months showed no differences between succimer-treated children and controls.⁷⁶ Succimer restores red blood cell D-aminolevulinic acid dehydratase activity, decreases erythrocyte protoporphyrin, and decreases

urinary excretion of D-aminolevulinic acid and coproporphyrin.^{18,27,51,52,76}

There is a large body of evidence reporting on the usage and safety profile of succimer in adults with chronic lead poisoning.^{13,17,27,40,43,44,47,48,59,61,69,83,100,103} The published experience outside the United States with the use of oral succimer for metal poisoning includes nearly 100 adult cases and contributes considerably to the supporting evidence. At least 74 additional individuals have been successfully treated parenterally (IM or IV) with the sodium salt of succimer.^{13,17,40,43}

ROLE FOR LEAD ENCEPHALOPATHY

The experience with the use of succimer in severely lead-poisoned patients, including those with encephalopathy, is limited.^{40,43,51} Three children with mean blood lead concentrations higher than 70 µg/dL who were treated with 5 days of succimer achieved comparable declines in blood lead concentration to two similar children who had been treated previously with a combination of BAL for 3 days and CaNa₂EDTA for 5 days.⁵¹ Three adult patients with encephalopathy achieved significant improvement following succimer chelation.⁴⁰ A 3 year-old child with a massive lead exposure superimposed on chronic lead poisoning and a blood lead concentration of 550 µg/dL was given BAL and CaNa₂EDTA for 5 days, with whole-bowel irrigation (WBI) performed on the first 3 days and succimer following WBI beginning on day 3 and continuing for 19 days. The blood lead concentration dropped from 550 to 70 µg/dL on day 5, but it rebounded to 99 µg/dL 2 days after BAL and CaNa₂EDTA—but not the succimer—were discontinued.⁴⁶

ROLE FOR ARSENIC EXPOSURE

Succimer has been used for arsenic toxicity in China and the Soviet Union since 1965.^{7,13} Animal studies with sodium arsenite and lewisite demonstrate the ability of succimer to improve the LD₅₀ with a good therapeutic index, lack of redistribution of arsenic to the brain as compared to BAL or control, and reduced kidney and liver arsenic concentrations.^{7,13,62,81,87} A few case reports attest to the ability of succimer to enhance the urinary excretion of arsenic^{31,88} and after 2 to 7 weeks of chelation urinary arsenic returned to normal concentrations following ingestion of arsenic trioxide ant bait by toddlers.¹⁰⁷ A randomized, placebo-controlled trial of succimer to treat 21 patients with chronic arsenic poisoning in India who had stopped ingesting arsenic contaminated water 5 months previously demonstrated improved clinical results and enhanced urinary excretion of arsenic in both the treatment and placebo groups, but no statistical differences could be demonstrated.⁷⁰ A comparison of BAL, succimer, and DMPS as arsenic antidotes demonstrated higher therapeutic indices for succimer and DMPS over BAL in chronic arsenic poisoning.⁷⁴

ROLE FOR MERCURY EXPOSURE

Succimer enhances the elimination of mercury and has been used to treat patients poisoned with inorganic, elemental, and methylmercury. It improves survival, decreases kidney damage, and enhances the elimination of mercury in animals following exposure to inorganic mercury^{4,22,54,57,65,84,110} and methylmercury.^{1,2,9,66} However, one study in mice subjected to intra-peritoneal mercuric chloride demonstrated an enhanced deposition of mercury in motor neurons following chelation with succimer or DMPS.³⁷ Of 53 construction workers who were exposed to mercury vapor, 11 received succimer and N-acetyl-dl-penicillamine in a crossover study.²⁰ Mercury elimination was increased during the period of succimer administration compared with the period of N-acetyl-d,l-penicillamine administration. Because the chelators were administered for only 2 weeks and late in the clinical course, therapeutic benefit could not be evaluated. When succimer was given to victims of an extensive Iraqi methylmercury exposure, blood methylmercury half-life decreased from 63 days to 10 days.⁷

ADVERSE EVENTS AND SAFETY ISSUES

Succimer is generally well tolerated with few serious adverse events reported.^{27,28,86,101} Common adverse events are typically GI in nature, including nausea, vomiting, flatus, diarrhea, and a metallic taste in 10% to 20% of patients. Rashes have been reported in about 4% of patients.²⁴ Some of these required discontinuation of the succimer. Mild elevations in aspartate aminotransferase and alanine aminotransferase are reported.^{21,26,28,52,64,79,111} Rarely, chills, fever, urticaria, reversible neutropenia, and eosinophilia are reported.^{18,27,28,47} Because neutropenia has been observed in some patients taking succimer and because bone marrow effects have been reported with other drugs in the same chemical class, the manufacturer's package insert recommends a complete blood count with a differential and a platelet count before and weekly during treatment.²⁴ During the latest open-label prospective study in children, apparently unrelated adverse events included an elevation in bone-derived alkaline phosphatase, eosinophils, and elevated serum aminotransferases.²⁷ One

patient developed severe hyperthermia and hypotension reportedly related to succimer administration.⁷⁹

The Chinese have reported a high incidence of more serious adverse effects (including dizziness and weakness) in response to IV or IM succimer.^{106,112} This discrepancy is undoubtedly related to the substantially greater dose of succimer delivered from parenteral administration compared with the relatively low (approximately 20%)⁷¹ oral bioavailability of succimer as a result of first-pass metabolism.

Incidental chelation of essential elements is always a concern with the use of chelators. A number of studies using succimer demonstrate no rise in urinary zinc, copper, iron, or calcium.^{27,40,43,50-52} Urinary excretion of essential elements was the focus of a study in a primate model of childhood lead exposure.⁹² Infant rhesus monkeys were exposed to lead for the first year of life to achieve blood lead concentrations of 40 to 50 µg/dL. Succimer was administered in the standard dosage regimen and complete urine collections over the first 5 days were analyzed for calcium, cobalt, copper, iron, magnesium, manganese, nickel, and zinc. Only when the data were analyzed collectively for all eight elements on all 5 days was there a statistically significant increased urinary elimination. These results raise concern that children subjected to repeated succimer chelation may also be at risk for enhanced elimination of essential elements.^{27,92,94} Therefore, children should be monitored and repleted as necessary. There is still relatively limited clinical experience with the xenobiotic, particularly with regard to long-term administration.

One concern with administering succimer orally is that outpatient management might permit continued unintentional lead exposure and the possibility for succimer-facilitated lead absorption. Studies with α-penicillamine, dimercaprol,⁵⁵ and CaNa₂EDTA demonstrate enhanced lead absorption and elevated blood lead concentrations.

Most blood lead concentrations are measured by graphite furnace atomic absorption spectrophotometry, in which case succimer does not interfere with the measurement. However, if blood lead concentrations were to be measured by anodic stripping voltammetry, succimer would affect the results by chelating the mercury in the electrode.²⁴ Succimer may cause a false-positive result for urinary ketones when tests using nitroprusside reagents (eg, Ketostix) are used, and a falsely decreased serum uric acid and creatine phosphokinase concentrations may be seen.²⁴

Animal studies suggest that succimer does not promote lead retention in the setting of continued exposure unless lead exposure is over-whelming.^{49,56,80} A radiolabeled lead tracer administered to adult volunteers suggested that succimer increased the net absorption of lead from the GI tract and may have distributed it to other tissues, as well as having enhanced urinary elimination.⁹³ Absorption is bimodal and consistent with an initial phase, followed by a delayed increase attributable to an enterohepatic effect. It may be that succimer-enhanced urinary lead elimination often exceeds enhanced lead absorption.⁸¹ One study reported two children with environmental exposure and dramatic rises in blood lead concentration while receiving succimer.²⁷ In the event of exposure to a new lead source, decontamination of the GI tract should complement oral succimer.⁷²

Although iron supplementation cannot be given concomitantly with BAL, because the BAL-iron complex may be a potent emetic, iron has been given concomitantly to patients receiving oral succimer without any adverse events.⁵³ The prevalence of both iron deficiency and elevated blood lead concentrations is highest among poor, inner-city children.⁶⁷ Because heme is a constituent of all cells, including those of the brain, it appears clinically indicated to provide iron supplementation during chelation therapy, when the heme pathway is freed of the inhibitory effects of lead. The timing of administration of the iron should be separate from administration of the succimer.²⁷

A case report describes a 3 year-old child who reportedly ingested 185 mg/kg of succimer and was asymptomatic.⁸⁹

PREGNANCY AND LACTATION

Succimer is FDA pregnancy category C. There are no adequate studies in pregnant women. The use of succimer in pregnancy is restricted to women who warrant therapy based on their symptoms.²⁷ There was a dose-dependent effect of succimer on early and late fetal resorption and on fetal body weight and length when succimer was administered to pregnant mice during organogenesis. No observed teratogenic effects were noted when 410 mg/kg, or approximately 5% of the acute LD₅₀, of succimer was administered subcutaneously.³⁶ However, doses of 410 to 1640 mg/kg/d of succimer administered subcutaneously to pregnant mice during organogenesis are teratogenic and fetotoxic, and doses of more than 510 mg/kg/d to pregnant rats also showed problems with reflexes in the offspring.²⁴ Succimer 30 to 60 mg/kg/d was administered by gavage to lead-poisoned rats from days 6 to 21 of gestation.²⁵ These doses of succimer decreased embryonic and fetal blood lead concentrations and normalized offspring body weight at 13 weeks. Although succimer was able to reverse some lead-induced immunotoxic effects, succimer itself caused problems with the immune system that persisted into adulthood.²⁵ Female mice exposed to lead in utero and then administered succimer from the fourth day of gestation to parturition demonstrated decreased blood lead concentrations; however, fetal liver and bone concentrations increased and worsened neural development in the offspring.¹⁰⁸ The use of succimer during pregnancy should only be undertaken if the potential benefit justifies the potential risk to the fetus.²⁴

COMBINED CHELATION THERAPY

Succimer can be combined with CaNa_2EDTA to take advantage of the ability of succimer to remove lead from soft tissues, including the brain, while capitalizing on the ability of CaNa_2EDTA to mobilize lead from bone.³⁰ A number of rodent models have examined this combination and found it to be superior in enhancing the elimination of lead, in reducing tissue concentrations of lead, and in restoring some lead-induced biochemical abnormalities.^{38,39,97} Although the addition of succimer to CaNa_2EDTA prevented the redistribution of lead to the brain caused by CaNa_2EDTA alone, the combination also increased urinary excretion of zinc, calcium, and iron.^{97,98} A retrospective review comparing dimercaprol plus CaNa_2EDTA to succimer plus CaNa_2EDTA in children with blood lead concentrations greater than 45 $\mu\text{g/mL}$, demonstrated a similar reduction in blood lead concentrations at the end of treatment and at 14 and 33 days following the termination of treatment.¹⁹ Blood lead concentration reductions were approximately 75%, 40%, and 37% at the end of therapy and at 14 and 33 days posttreatment, respectively. The succimer plus CaNa_2EDTA combination was better tolerated.

DOSING AND ADMINISTRATION

The dosage is 350 mg/m^2 in children, three times a day for 5 days, followed by 350 mg/m^2 twice a day for 14 days. In adults, the dosage is 10 mg/kg three times a day for 5 days followed by 10 mg/kg twice a day for 14 days. At approximately 5 years of age, dosing based on body surface area approximates the 10 mg/kg dose, while for children younger than 5 years of age dosing by body surface area, as was done during the premarketing trials, gives higher doses and is recommended.^{29,73} Repeated courses may be needed depending on the blood lead concentration. However a minimum of 2 weeks between courses is recommended unless blood lead concentrations mandate otherwise.²⁴ For patients who cannot swallow the capsule whole, it can be separated immediately prior to use and the contents sprinkled into a small amount of juice or on apple sauce, ice cream, or any soft food, or placed on a spoon and followed by a fruit drink (Table A26–1).

TABLE A26-1 A and B. Examples of Dosing Calculations

A. Succimer (available as 100-mg bead-filled capsules)					
	Avg. Height (in.)	Avg. Weight (lbs.)	m^2	350 mg/m^2 ^a	10 mg/kg ^a
<i>Child</i>					
2 year-old boy	36	30.5	0.593	189 mg	
2 year-old girl	35	29	0.57	200 mg	
4 year-old boy	42	39.75	0.73	255 mg	
4 year-old girl	41.75	38.75	0.72	250 mg	
<i>Adult</i>					
50 kg					500 mg
70 kg					700 mg
90 kg					900 mg
B. Chemet (Succimer) Pediatric Dosing Chart					
Pounds	Kilograms	Dose (mg) ^a	Number of Capsules ^a		
18–35	8–15	100	1		
36–55	16–23	200	2		
56–75	24–34	300	3		
76–100	35–44	400	4		
100	>45	500	5		

^aTo be administered every 8 hours for 5 days, followed by dosing every 12 hours for 14 days.

FORMULATION

Succimer (Chemet) is available as 100-mg bead-filled capsules.

SUMMARY

- Succimer (meso-2,3-dimercaptosuccinic acid) is an orally active metal chelator that is FDA approved for the treatment of lead poisoning in children with blood lead concentrations higher than 45 µg/dL.
- There is no evidence at this time that succimer improves cognitive performance in patients with blood lead concentrations lower than 45 µg/dL.
- Succimer is also used to treat patients poisoned with arsenic and organic and inorganic mercury.
- The advantages of succimer use include oral administration, limited effects on trace metals such as zinc, enhanced patient tolerance, limited toxicity, and the ability to coadminister iron (if needed). It is not contraindicated in glucose-6-phosphate dehydrogenase-deficient individuals.
- By contrast to CaNa_2EDTA , succimer does not redistribute lead to the brain of poisoned animals.^{11,30}

A27 ANTIDOTES IN DEPTH

Edetate Calcium Disodium (CaNa_2EDTA)

Mary Ann Howland

INTRODUCTION

Edetate calcium disodium (CaNa_2EDTA) is a chelator that is primarily used for the management of severe lead poisoning (blood lead concentrations >70 mg/dL) in conjunction with dimercaprol (British anti-Lewisite {BAL}). Edetate calcium disodium has been replaced by succimer (2,3-dimercaptosuccinic acid) for the treatment of patients with lead concentrations between 45 and 70 $\mu\text{g/dL}$. Recently, in a clinical trial with much criticism, disodium EDTA (Na_2EDTA) (not approved by the US Food and Drug Administration {FDA} and extemporaneously compounded) was demonstrated to produce some reduction in adverse cardiovascular outcomes in patients with a history of myocardial infarction.^{3,21,32,38} This preparation is not to be used for lead chelation due to the potential for life-threatening hypocalcemia.

HISTORY

Ethylenediaminetetraacetic acid (EDTA) was first discovered and synthesized in the 1930s. In the late 1940s, it was approved by the FDA as a food additive. Work on using CaNa_2EDTA for lead toxicity began in the 1950s. At the same time, investigation into the uses of EDTA for the reversal of cardiovascular disease began. The CaNa_2EDTA mobilization test was once widely recommended as a diagnostic aid for assessing the potential benefits of chelation therapy.^{35,36} Currently, it can only be considered obsolete.^{14,18,21} Criticisms of the test include difficulties with administration of the antidote, unreliability as a predictor of total-body lead burden, expense, and the risk of worsening toxicity through redistribution of lead to either the kidney or the brain.¹⁸

PHARMACOLOGY

Chemistry

Edetate calcium disodium is an ionic, water-soluble compound with a molecular weight of 374.27 (anhydrous) and a formula of $\text{C}_{10}\text{H}_{12}\text{CaNa}_2\text{O}_8$.

Mechanism of Action

Edetate calcium disodium belongs to the family of polyaminocarboxylic acids. Although it is capable of chelating many metals, its current use is almost exclusively in the management of lead poisoning. The term chelate has its origin in the Greek word chele, which means 'claw,' implying an ability to tightly grasp the metal.⁴⁸ Implicit in chelation is the formation of a ring-structured complex. When CaNa_2EDTA chelates lead, the calcium is displaced and the lead takes its

place, forming a stable ring compound.³⁰ Bone is the primary source of lead chelated by CaNa_2EDTA . Blood lead concentration drops due to urinary elimination; however, once chelation is stopped, redistribution to soft tissues, including the brain, and then, ultimately, the return of lead to bone occurs.¹¹ Zinc is also capable of displacing calcium and forming a stable chelate, whereas copper and mercury are not.¹¹

PHARMACOKINETICS AND PHARMACODYNAMICS

Edetate calcium disodium is a highly polar drug with a small volume of distribution (V_d) due to its polar nature and approximates that of the extracellular fluid compartment in normal individuals,^{25,30} but the V_d is less in patients with renal dysfunction.³⁹ Edetate calcium disodium appears to penetrate erythrocytes poorly,^{2,25} and less than 5% of CaNa_2EDTA gains access to the spinal fluid.^{25,30} Oral administration of CaNa_2EDTA is not practical because of an oral bioavailability of less than 5%. The half-life is about 20 to 60 minutes.^{6,25,30} Renal elimination approximates the glomerular filtration rate,³⁷ which correlates with creatinine clearance,⁹ resulting in the excretion of 50% of CaNa_2EDTA in the urine within 1 hour, and more than 95% within 24 hours.^{25,30} Elimination is all kidney with no appreciable metabolism. When CaNa_2EDTA combines with lead, it forms a stable, soluble, nonionized compound subsequently excreted in the urine. Following CaNa_2EDTA administration, urinary lead excretion is increased 20-to 50-fold.^{13,40}

ROLE IN LEAD EXPOSURE

Animals

Animal studies demonstrate a decrease in tissue lead stores, including brain concentrations, when measurements are performed following CaNa_2EDTA therapy.²⁸ A rat study examining the effect of a single dose of CaNa_2EDTA on brain lead concentrations demonstrated a significant increase in brain lead concentrations,²¹ suggesting that CaNa_2EDTA may initially mobilize lead and facilitate redistribution to the brain. Additional doses enhance lead elimination, reduce blood lead concentrations, and subsequently reduce brain lead concentrations. The initial increase in brain lead may explain why some human case reports demonstrate worsening lead encephalopathy when CaNa_2EDTA is used without concomitant dimercaprol (BAL) chelation therapy.

Humans

Edetate calcium disodium is capable of reducing blood lead concentrations, enhancing renal excretion of lead, and reversing the effects of lead on hemoglobin synthesis.¹⁸ With chronic lead exposure, blood lead concentrations rebound considerably in the days to weeks following cessation of CaNa_2EDTA .^{1,2,27} Although CaNa_2EDTA has been used clinically since the 1970s, no rigorous clinical studies have ever been performed to evaluate whether CaNa_2EDTA is capable of reversing the neurobehavioral effects of lead.^{19,20} Chelators are incapable of dramatically decreasing the body burden of lead, because only several milligrams of lead are eliminated during chelation.^{13,15,41} Children evaluated with blood lead concentrations of 25 to 50 $\mu\text{g}/\text{dL}$ who were given CaNa_2EDTA for 5 days revealed very little difference in blood lead, bone lead, or erythrocyte protoporphyrin concentrations, when compared with pretreatment values.³³ A study in children demonstrated no additional benefits of CaNa_2EDTA on cognitive performance beyond that which was achieved by limiting further lead exposure and correcting an iron deficiency anemia.^{40,42} A follow-up study in children with initial blood lead concentrations between 25 and 55 $\mu\text{g}/\text{dL}$ also suggested an interaction between initial iron status, blood lead concentration, and an improvement in perceptual motor performance over a 6-month period. Both the correction of iron deficiency and a reduction in blood lead concentration (accomplished with limiting further exposure and or CaNa_2EDTA chelation) contributed to the improvement, emphasizing a critical need to correct iron-deficiency anemia as well as limit lead exposure.⁴³

ADVERSE EVENTS AND SAFETY ISSUES

The principal toxicity of CaNa_2EDTA is related to the metal chelates it forms. In mice, the intraperitoneal (IP) LD_{50} values of various CaNa_2EDTA metal chelates are CaNa_2EDTA , 14.3 mmol/kg; lead EDTA, 3.1 mmol/kg; and mercury EDTA, 0.01 mmol/kg.

When CaNa_2EDTA is given to patients with lead poisoning, the resultant sites of major renal toxicity are the proximal convoluted tubule, the distal convoluted tubule, and the glomeruli, possibly caused by the release of lead in the kidneys

during excretion.³⁰ Of the 130 children who received both dimercaprol and CaNa₂EDTA, 13% had biochemical evidence of nephrotoxicity, and 3% developed acute oliguric renal failure, which resolved over time; none needed hemodialysis.³⁶ Other studies failed to demonstrate any cases of renal failure in more than 1000 patient courses of therapy when CaNa₂EDTA was given in divided daily doses of 1000 mg/m² intravenously (IV) over 1 hour every 6 hours.³⁴ Because lead toxicity causes renal damage independent of chelation, it is important to monitor renal function closely during CaNa₂EDTA administration and to adjust the dose and schedule appropriately.^{37,38} Nephrotoxicity may be minimized by limiting the total daily dose of CaNa₂EDTA to 1 g in children or to 2 g in adults, although higher doses may be needed to treat lead encephalopathy. Continuous infusion while maintaining good hydration increases efficacy and decreases toxicity.³⁷ Because the administration of disodium EDTA can lead to life-threatening hypocalcemia and death, CaNa₂EDTA is the preparation of choice for lead toxicity and hypocalcemia is no longer a clinical concern.^{4,9} Other adverse clinical effects of CaNa₂EDTA, most of which are uncommon, include malaise, fatigue, thirst, chills, fever, myalgias, headache, anorexia, urinary frequency and urgency, sneezing, nasal congestion, lacrimation, glycosuria, anemia, transient hypotension, increased prothrombin time, and inverted T waves.^{11,30} Various mucocutaneous lesions in two patients included cheilosis and sore throat, magenta tongue, and papular lesions over the face, trunk and extremities, attributed to zinc deficiency.⁷ Mild increases in alanine aminotransferase and aspartate aminotransferase, which are usually reversible, and decreases in alkaline phosphatase are frequently reported. Extravasation may result in the development of painful calcinosis at the injection site.^{40,44} Depletion of endogenous metals, particularly zinc, and perhaps iron, and manganese, can result from chronic therapy.^{12,47} An animal study suggests that gastrointestinal lead absorption may be enhanced by either IP or oral administration of CaNa₂EDTA²⁹; consequently, removal of lead from the environment should always remain the first strategy in the management of lead toxicity. In the event of exposure to a new lead source, decontamination of the gastrointestinal tract must complement chelation.³⁵

PREGNANCY AND LACTATION

Although CaNa₂EDTA is FDA pregnancy category B, there are no adequate and well-controlled studies in pregnant women and a risk-to-benefit analysis must be made if its use is considered. It is not known whether CaNa₂EDTA is excreted in human milk, but Briggs considers breast-feeding a contraindication.⁸

In a model of lead poisoning in pregnant rats, fetal resorption decreased and the number of live fetuses increased when CaNa₂EDTA was used, although the placental concentrations of lead were increased.²³ Zinc concentrations were not affected. However, another study found that when CaNa₂EDTA was given to pregnant rats not poisoned with lead, increases in submucous clefts, cleft palate, adactyly/syndactyly, curly tail, and abnormal ribs and vertebrae resulted.¹⁰ These teratogenic effects occurred with doses of CaNa₂EDTA comparable to human doses and without causing noticeable changes in the mother except for weight gain. Use of zinc calcium EDTA and zinc EDTA preparations in pregnant rats caused no teratogenic effects at low doses, but resulted in the development of submucous cleft palates in 30% of the offspring receiving the higher dose of zinc calcium EDTA.¹⁰ Another study in rats with doses 25 to 40 times that used in humans revealed fetal malformations that were prevented by simultaneous zinc supplementation.¹¹

DOSING AND ADMINISTRATION

There has never been a clinical trial to identify the best dose of CaNa₂EDTA or how best to administer the dose. The most commonly recommended dose is determined by the patient's body surface area or weight (up to a maximum dose), the severity of the poisoning, and renal function (Chap. 96; [Tables 96-8 and A27-1](#)).^{18,33,40} For patients with lead encephalopathy, the dose of CaNa₂EDTA is 1500 mg/m²/d, approximately 50 to 75 mg/kg/d, by continuous IV infusion, starting 4 hours after the first dose of dimercaprol and after an adequate urine flow is established.¹⁷ The dose in obese patients has not been studied. A maximum dose of 3 g is suggested. Simultaneous dimercaprol and CaNa₂EDTA therapy is administered for 5 days, followed by a rest period of at least 2 to 4 days, which permits lead redistribution. For adults with lead nephropathy, the following dosage regimen is recommended: 500 mg/m² every 24 hours for 5 days for patients with a serum creatinine of 2 to 3 mg/dL; every 48 hours for three doses for a serum creatinine of 3 to 4 mg/dL; and one dose for a serum creatinine concentration higher than 4 mg/dL.¹¹ Previous recommendations were to limit the daily dose to 50 mg/kg when CaNa₂EDTA is used in patients with renal dysfunction.^{25,37,39} There is limited evidence to suggest that folic acid, pyridoxine, and thiamine increase the efficacy of CaNa₂EDTA⁴⁵; therefore, data are inadequate to recommend their routine administration. A blood lead concentration should be measured one hour after the CaNa₂EDTA infusion is discontinued in order to avoid falsely elevated blood lead concentration determinations.

TABLE A27-1. Calculations for IV Edetate Calcium Disodium Infusion Over 24 hours

	Avg. Height (in.)	Avg. Weight (lbs.)	m ³	1000 mg/m ² Over 24 hours IV	Dilute in D ₅ W or NS and Infuse Over 24 Hours ^a	1500 mg/m ² Over 24 Hours IV	Dilute in D ₅ W or NS and Infuse Over 24 Hours ^a
Child^b							
2 year-old boy	36	30.5	0.593	593 mg	200 mL	890 mg	300 mL
2 year-old girl	35	29	0.57	570 mg	200 mL	855 mg	300
4 year-old boy	42	39.75	0.73	730 mg	250	1095 mg	400
4 year-old girl	41.75	38.75	0.72	720 mg	250	1080 mg	400
Adult^{c,d}							
50 kg			1.5	1500 mg	500 mL	2250 mg	750 mL
70 kg			1.8	1800 mg	600 mL	2700 mg	1000 mL
90 kg			2.1	2100 mg	700 mL	3000 mg	1000 mL

Edetate calcium disodium comes in 5-mL ampules of 200 mg/mL.

^aDilute in D₅W or 0.9% NaCl to concentrations of less than 0.5% to avoid thrombophlebitis with IV administration. Be mindful of total fluid requirements if encephalopathic to avoid cerebral edema. If fluid is an issue consider intramuscular injection, otherwise infuse IV over 24 hours. ^bDo not exceed the adult dose. ^cFor adults with lead nephropathy, the following dosing regimen has been suggested: 500 mg/m² every 24 hours for 5 days for patients with serum creatinine concentrations of 2–3 mg/dL, every 48 hours for three doses for patients with creatinine concentrations of 3–4 mg/dL, and once weekly for patients with creatinine concentrations above 4 mg/dL. ^dThe dose in obese patients has not been studied. A maximum dose of 3 g seems reasonable.

D₅W = 5% dextrose in water; IV = intravenous; NS = 0.9% sodium chloride solution.

In symptomatic children without manifestations of lead encephalopathy, the dose of CaNa₂EDTA is 1000 mg/m²/d, approximately 25 to 50 mg/kg/d, in addition to dimercaprol at 50 mg/m² every 4 hours. However, with the FDA approval of succimer, and the demonstrated ability to reduce brain lead concentrations in animals, succimer has essentially replaced CaNa₂EDTA as the chelator of choice in lead-poisoned children without encephalopathy and lead concentration less than 70 µg/dL.^{15,27}

Due to the pain associated with intramuscular (IM) administration, it is recommended that CaNa₂EDTA be administered at concentrations of approximately 0.5% by continuous IV infusion over 24 hours in 5% dextrose or 0.9% NaCl.¹⁸ The package insert recommends infusing the dose over 8 to 12 hours.¹¹ Higher concentrations may lead to thrombophlebitis. Edetate calcium disodium is incompatible with other solutions. Careful attention to total fluid requirements in children and patients who have or who are at risk for, lead encephalopathy is paramount.^{30,40} Rapid IV infusions in patients with lead encephalopathy may increase intracranial pressure and cerebral edema. In children with acute lead encephalopathy, starting BAL 4 hours prior to CaNa₂EDTA appears to be more effective than starting CaNa₂EDTA prior to and simultaneously with BAL.^{16,19} In addition, treating with two chelators also reduces the blood lead concentration significantly faster than CaNa₂EDTA alone, while maintaining a better molar ratio of chelator to lead.¹⁶

If CaNa₂EDTA is to be administered IM to avoid the use of an IV and fluid overload, then either procaine or lidocaine is added to the CaNa₂EDTA in a dose sufficient to produce a final concentration of 0.5% (5 mg/mL). This can be accomplished by mixing 1 mL of a 1% procaine or 1% lidocaine solution with each mL of chelator.^{11,30} The procaine or lidocaine minimizes pain at the injection site.

COMBINATION THERAPY WITH SUCCIMER OR DMPS

The possible benefit of combining CaNa₂EDTA with succimer or 2,3-dimercapto-1-propane-sulfonic acid (DMPS) is under investigation in animals.^{22,24,46} The combination of CaNa₂EDTA with succimer appears more potent than either individual chelator in promoting urine and fecal lead excretion, and decreasing blood and liver lead concentrations. However, this approach may increase zinc depletion.⁴⁶

A retrospective analysis compared the combination of BAL and CaNa₂EDTA with succimer and CaNa₂EDTA in children with blood lead concentrations of about 35 to 70 µg/dL (up to 90 µg/dL for the BAL group).⁵ Equivalent reductions in blood lead concentrations were demonstrated with fewer adverse events in the succimer group. One case report of a child with lead encephalopathy and an extremely high blood concentration of 550 µg/dL employed initially a combination of BAL and CaNa₂EDTA followed by succimer, but a rebound increase in the lead concentration resulted in the addition of CaNa₂EDTA.²⁶ More data are needed to confirm this approach.

FORMULATION

Edetate calcium disodium is available as calcium disodium versenate in 5-mL ampules containing 200 mg of CaNa_2EDTA per mL (1 g per ampule).³⁰ Disodium edetate (sodium EDTA) should not be considered an alternative to CaNa_2EDTA because of the risk of life-threatening hypocalcemia associated with sodium EDTA use.

SUMMARY

- Edetate calcium disodium reduces blood lead concentrations, enhances urinary lead excretion, and reverses lead-induced hemato-logic effects.
- Edetate calcium disodium remains the standard of care for patients with lead encephalopathy when used in conjunction with dimercaprol.
- The first dose of dimercaprol should precede the first dose of CaNa_2EDTA by 4 hours.
- Recommended doses and schedules should not be exceeded and should be reduced when the creatinine clearance is reduced.
- Patients should be well hydrated to achieve an adequate urine flow prior to and during CaNa_2EDTA therapy.

Manganese (Mn)

Atomic number	=	25
Atomic weight	=	54.94 Da
Normal concentrations		
Whole blood	=	4–15 µg/L
Serum	=	0.9–2.9 µg/L
Urine	<	10 µg/L

HISTORY AND EPIDEMIOLOGY

Manganese is the 12th most abundant element in the Earth's crust (0.106%). The name manganese derives from Magnesia, a prefecture of Thessaly in ancient Greece. Ores from this region are particularly abundant in manganese oxides and carbonates. Manganese salts are brightly pigmented and the earliest known uses were artisanal. Manganese dioxide was found in prehistoric paints and was used as a decolorant in glassmaking during the Roman Empire.

Adding manganese to iron produces a stronger metal alloy, and manganese-iron alloys are found in weapons from ancient Sparta. By the early 19th century, manganese became an important component in the manufacture of steel, which remains the largest industrial use of manganese today. Currently, more than 85% of manganese is used in the production of ferromanganese alloys. Manganese chloride is used in dry-cell battery manufacture and the metal is a catalyst for chlorination of organic compounds, manganese dioxide is used in batteries and glass production, and manganese sulfate is used to make ceramics, fungicides, and pesticides.

Most reported cases of manganese toxicity, or manganism, are associated with occupational exposure. Manganism was first described in 1837, when the development of a characteristic neuropsychiatric syndrome in French pyrolusite mill workers was linked with exposure to high concentrations of manganese oxide dusts.²⁰ Manganese, primarily in the form of oxides, is released during mining, and inhalation exposure to dusts from grinding manganese ore has historically been the most important source of manganese toxicity. Inhalation of inorganic manganese compounds may also occur during smelting, welding, or burning of coal, oil, or fuel containing manganese compounds. A neuropsychiatric syndrome in welders has been attributed to the inhalation of manganese oxide fumes.^{12,14,37,46,68}

Manganism has also been described in several nonoccupational settings. Manganese chloride and manganese sulfate are employed as nutritional supplements,⁹ and manganese toxicity is well documented in patients receiving excessive doses in total parenteral nutrition.^{24,52,58} Infants, young children, and patients with impaired clearance from chronic liver disease are particularly at risk. More recently, epidemic manganese toxicity has been reported from the use of intravenous psychostimulant drugs such as methcathinone and a “Russian cocktail” prepared using potassium permanganate as an oxidizing agent.^{41,79}

Environmental exposure to excessive manganese in drinking water has been linked to neurodevelopmental deficiencies in children, including effects on cognition, behavior, memory, and motor function.^{11,18,39} Concerns have also been raised about the potential environmental health risks of methylcyclopentadienyl manganese tricarbonyl (MMT), an antiknock agent added to gasoline as an alternative to lead.^{22,31} MMT has been allowed in Canada since 1976 and in the United States since 1995; however, more research is needed to understand its contribution to the environmental burden of manganese and to human health.⁷⁶

Potassium permanganate was first discovered to be a strong oxidizer in the 18th century. Weak solutions of potassium permanganate 0.01% are still used in medicine as topical drying and antiseptic skin preparations. Potassium, sodium, and barium permanganate also have uses in the pharmaceutical, chemical, and photographic industries. The toxicity of permanganates is mostly related to their oxidizing effects and is not discussed here.

CHEMISTRY

Manganese is a transition metal with atomic number 25, located between chromium and iron in the periodic table. It is dark-grey, brittle paramagnetic, and occurs in several mineral forms. Most manganese in the environment is found complexed to oxygen, carbon, or chloride. The most economically important ore is pyrolusite, or manganese dioxide (MnO_2), from which metallic manganese was first isolated in 1774.

Manganese can exist in oxidation states from -3 to $+7$. Divalent manganese (Mn^{2+}) is the most common, the most bioavailable, and the most physiologically important form. Mn^{3+} is also biologically important and is, for example, the form of manganese in superoxide dismutase.

PHARMACOLOGY AND PHYSIOLOGY

Manganese is an essential dietary element found in nuts, grains, legumes, fruits, and vegetables. Most people consume 2 to 9 mg of manganese compounds per day, but vegetarians may consume more. Manganese salts in well water also contribute to dietary intake.⁷³ Manganese is present in human breast milk in its trivalent form bound to lactoferrin, which is readily absorbed via receptors in the small intestine. Manganese salts—usually manganese sulfate or manganese chloride—are typically added to infant formulas, processed foods, and dietary supplements, although these are less well absorbed.

Manganese is a cofactor in many human enzyme systems, including superoxide dismutase, hexokinase, xanthine oxidase, and glutamine synthase. It is also present in several metalloproteins.⁹ Although deficiency in humans is not reported, experimental manganese restriction produced a scaling, erythematous, pruritic rash, alterations in calcium homeostasis (eg, hypercalcemia, hyperphosphatemia), and increased alkaline phosphatase in healthy volunteers.²⁷

Normally, less than 5% of dietary manganese is absorbed throughout the length of the small intestine. However, enteral manganese absorption may be altered depending on the dietary needs of the host and the presence of similarly charged compounds in the diet. For example, divalent manganese ion (Mn^{2+}) forms complexes with a variety of ligands in the body and can substitute for Mg^{2+} , Ca^{2+} , and Fe^{2+} in complexes with proteins and enzymes.⁵⁴ Because manganese can compete with iron for binding sites on transferrin, the percentage of absorbed manganese is increased in the presence of iron-deficiency anemia. Radioisotope studies demonstrate that absorption of dietary manganese is doubled in individuals with anemia.^{9,26} Manganese absorption from the gastrointestinal tract is also inversely proportional to the amount of calcium in the diet, most likely because of competition between divalent cations for transport.⁹

About 85% of manganese in the blood is bound to hemoglobin in erythrocytes, and normal measured whole blood concentrations may be as much as five times higher than those measured in serum.⁶³ The remaining manganese in plasma is mostly bound to transferrin, β_1 -globulin, and albumin.⁵ Manganese is widely distributed to all tissues, and crosses both the placental⁹ and the blood–brain barriers.⁶ Transport in the body is facilitated by transport proteins and for Mn^{2+} by the divalent metal transporter.⁹

Manganese is primarily eliminated via the bile in feces. It accumulates in bile against a concentration gradient, which suggests an active transport mechanism.⁴⁰ Renal excretion is negligible, whereas 67% of a radio-labeled manganese dose injected intravenously is recovered in feces within 48 hours, and less than 0.1% appears in the urine within 5 days of administration.⁴⁰

The elimination half-life of manganese from the body is approximately 40 days,⁵⁰ but this value is highly variable among individuals. Elimination of manganese may be prolonged in young women with high ferritin stores²⁶ or after the initiation of oral iron therapy for anemia.⁵⁰ This effect is most likely due to increased hepatic sequestration from increased production of iron transport and storage proteins. High concentrations of manganese are found in patients with hemochromatosis, supporting the idea that increased or abnormal iron storage proteins will also lead to increased hepatic manganese stores.¹

PATHOPHYSIOLOGY

Manganese toxicity may be due to overexposure or impaired elimination. Because of its low enteral absorption, excessive dietary ingestion of manganese is unlikely to cause toxicity in adults with normal elimination. Parenteral administration of either nutritional supplements or xenobiotics containing manganese presents a greater toxicologic risk. The major occupational route of exposure is inhalation of manganese dusts or fumes. Inhalation may acutely elevate blood concentrations, and possibly create pulmonary manganese deposits that prolong exposure and absorption even following patient removal from the environmental source.⁵⁹ Whereas normal liver function may protect against accumulation of manganese in soft tissue, patients with hepatic disease are at risk for manganese bioaccumulation and toxicity from normal dietary intake.^{64,70,74}

Although manganese is widely distributed in the body, major clinical features of manganese toxicity are primarily related to its accumulation in brain. Manganese is deposited throughout cerebral tissue but concentrates in the basal ganglia structures and, to a lesser extent, in the caudate and putamen. The exact mechanisms of manganese uptake into neurons and its transport within the brain are still being elucidated.³ Manganese influx into the central nervous system appears to involve several transport mechanisms. Transferrin-receptor mediated endocytosis of transferrin-bound manganese is thought to be the major route of entry under normal conditions.⁶ However, for unclear reasons nonprotein-bound manganese appears to cross the blood brain barrier more quickly than protein-bound manganese.^{57,67} Therefore, exposure to manganese in excess of blood ligand-binding capacity may promote its distribution to the brain. Transferrin may also play an important part in manganese accumulation in the basal ganglia, specifically, because these are areas of high transferrin-receptor density.^{5,23} The divalent-metal transporter is most likely also important, but more research is needed to understand its role.

The specific mechanisms of manganese neurotoxicity are also not well established, although oxidative stress, mitochondrial dysfunction, neuroinflammation, and alterations in neurotransmitter metabolism are all likely implicated. Mn^{2+} concentrates in mitochondria and inhibits both mitochondrial F1-ATPase and complex I in the electron transport chain, thereby disrupting oxidative phosphorylation and contributing to energy failure and cytotoxicity.^{16,28,29,87,88} Like other transition metals, manganese causes local damage by generating reactive oxygen species during redox cycling between the divalent and trivalent forms. The participation of manganese in Fenton reactions also occurs and results in oxidative tissue damage (Chap. 12). Manganese may also promote inflammatory neuronal injury by potentiating the release of nitric oxide, prostaglandin E1, TNF- α , and other inflammatory mediators from activated glial cells.^{25,47,56}

The clinical features of manganism share many similarities with idiopathic Parkinson disease (PD). Degeneration of nigrostriatal dopaminergic neurons is clearly implicated in PD, and the above mechanisms would suggest that this is also the case in manganese-induced neurotoxicity. However, newer evidence indicates that dopamine synthesis and dopamine transporters may be normal in patients with manganese related motor dysfunction.³⁰ By contrast, single photon emission computed tomography (SPECT) and positron emission tomography (PET) studies in patients with PD show decreased presynaptic dopamine terminal markers in the striatum and reduced dopa decarboxylase activity. Although neuroimaging and neurochemical studies in patients with manganism are quite limited, the hypothesis that manganese does not cause neurodegeneration but rather an inability to release available dopamine bears further exploration.

CLINICAL MANIFESTATIONS

Early reports of manganism in German manganese workers⁹ and Chilean miners⁷⁵ described an acute phase characterized by psychiatric symptoms known as “manganese madness” and included visual hallucinations, behavioral changes, anxiety, impotence, and decreased libido.⁹ Currently accumulated evidence indicates that psychiatric and/or cognitive abnormalities such as attentional and memory deficits are common. However, classic manganism is best typified by a late-presenting syndrome of extrapyramidal movement abnormalities, including marked bradykinesia, rigidity, postural instability, loss of facial expression, impaired speech, and pronounced gait disturbance.⁸ Signs and symptoms vary with duration and level of exposure, may be insidious in onset, and may not become apparent for several years (Table 97–1). More work is needed to describe how these evolve, as well as to understand the relevance of subtle preclinical neuropsychological signs for predicting sequelae.

TABLE 97–1. Typical Features of Chronic Manganism

<i>System</i>	<i>Early Manifestations</i>	<i>Late Manifestations</i>
Constitutional	Asthenia, lethargy	—
Gastrointestinal	Anorexia	—
Neurologic	Fine intention tremor Headaches	Coarse intention tremor Visual hallucinations Cognitive impairment Loss of facial expression Dysphagia Micrographia Gait instability ^a Low-volume speech
Psychiatric	Apathy Irritability Emotional lability	Decreased libido or impotence Anxiety Additional behavioral changes
Musculoskeletal	Arthralgias	Muscle rigidity

^aDecreased arm swing, toe walking, and inability to turn or walk backward without falling.

Although the movement disorder that typically occurs in patients with manganism is similar to that seen in cases of idiopathic PD, including a typical “cock walk” on the balls of the feet, there are several distinguishing clinical features, including a lack of or atypical tremor, a particular tendency to fall backward, and an absence of severe progressive dementia.^{30,38} Cognitive impairment or vestibular–auditory dysfunction is typically mild, if present at all. In addition, an absent or unsustained clinical response to levodopa therapy may be considered a criterion for establishing a diagnosis of clinically probable manganism.⁶² Although symptomatic improvement with levodopa therapy has been reported in some patients,^{19,53,68} most evidence indicates that dopamine supplementation does not improve signs and symptoms of parkinsonian in patients with manganese associated neurotoxicity.^{30,42,49,79}

Acute inhalational exposure to high concentrations of manganese oxides can cause metal fume fever (Chaps. 91 and 124), with characteristic fever, chills, nausea, headache, myalgias, and arthralgias.⁹ Chronic occupational exposure to manganese oxide fumes is also associated with chemical pneumonitis and increased rates of bronchitis and pneumonia, but it does not appear to cause pulmonary fibrosis.^{48,69} Manganese exposure is also associated with neurodevelopmental deficits^{11,18,39} and hypertension.⁴⁵

DIAGNOSTIC TESTING

Manganism may be difficult to differentiate from other neurodegenerative disorders. Several tests may contribute to establishing the diagnosis, but each has important limitations. Careful consideration of plausible sources of exposure, findings on neurologic and neuropsychologic examinations, and determining hepatic function and iron reserve status are important. If movement abnormalities are present, then failure of sustained response to levodopa therapy is highly suggestive of manganism. Genetic mutations in the manganese transporter SLC30A10 have recently been linked to a neurodegenerative syndrome, and family history should also be explored.^{66,83}

Normal reference values for manganese in blood and urine are published (see above) and measurements may be helpful, but concentrations are poorly correlated with total body manganese burden. Whole blood manganese concentrations are the most reliable values for biomonitoring purposes, although they only correlate with group and not with individual exposures.^{7,9} Manganese concentrations in blood are most commonly determined by flame or furnace atomic absorption spectrophotometry. Whole blood manganese concentrations should be elevated after acute overexposure, but abnormal concentrations are neither sensitive nor specific for chronic manganese toxicity because manganese is rapidly cleared from the blood.⁸⁶ Signs and symptoms of manganism are insidious and may occur long after concentrations in urine or blood have normalized.

Urine manganese concentrations are not well correlated with either symptoms or extent of exposure.⁷ Increased urinary elimination of manganese after chelation challenge with calcium disodium ethylenediaminetetraacetic acid (CaNa₂EDTA) occurs but cannot be interpreted. In most situations, it is unclear whether the increased excretion signifies mobilization of physiologic manganese, an increased body burden of manganese, or toxicity. The utility of hair, nail clippings, and saliva as

biomarkers of chronic manganese exposure is not clearly established.^{7,44,78,84}

Patients with manganese associated movement disorders often have a characteristic pattern of abnormalities on magnetic resonance imaging (MRI) that includes a bilateral, symmetric, hyperintense signal in the basal ganglia, particularly in the globus pallidus, on T1-weighted images.^{4,37,38,61,79} This pattern is also reported in patients with iatrogenic manganism from long-term parenteral nutrition,^{10,24,36,55,81} and is sometimes seen in cirrhotic patients with impaired dietary manganese elimination.^{32,65,77} MRI studies in patients receiving total parenteral nutrition (TPN) have shown a positive correlation between the concentration of manganese in TPN mixtures and the intensity of increased basal ganglia signal on T1-weighted MRI images.^{10,81} An increased T1-weighted MRI signal throughout the basal ganglia has been demonstrated in welders and correlates with the length of welding exposure.²¹ These changes on MRI are reversible with TPN discontinuation in patients without neurologic symptoms.^{55,80} While highly suggestive of manganism in the correct clinical context, an increased T1-weighted signal in the basal ganglia is a nonspecific finding that may also reflect iron, copper or lipid deposition, hemorrhage, or neurofibromatosis.⁹

By contrast to these radiographic abnormalities, MRI findings in PD typically demonstrate a hypointense signal in the substantia nigra on T2-weighted images.^{43,82} Some evidence suggests that SPECT and PET may also help differentiate these two clinical entities. For example, molecular imaging studies of patients with chronic manganese exposure and extrapyramidal symptoms have largely failed to demonstrate abnormal nigrostriatal dopaminergic activity and projections, although these are clearly abnormal in patients with PD.^{30,61,85}

TREATMENT

Treatment for manganese toxicity is primarily supportive. Discovery and removal from the source of exposure is paramount, although clinical manifestations may still progress as manganese body stores fall.³⁵ Antiparkinsonian therapy is generally ineffective or has limited benefit in relieving motor symptoms. Antioxidant therapy has been proposed, based on the hypothesis that oxidant stress and mitochondrial dysfunction contribute to manganese induced cellular damage, but human data are lacking.^{15,17,33}

The clinical utility of chelation therapy in patients with manganese toxicity has not been well studied and remains controversial. Treatment with CaNa_2EDTA was reportedly useful in some cases (Antidotes in Depth: A27).³⁴ More often, chelation improves urinary excretion of manganese without affecting neurologic manifestations of toxicity.^{13,79} Chelation with dimercaptosuccinic acid had no effect on either manganese concentrations in blood and urine or on clinical signs of manganism in two patients.²

Treatment with the iron chelator deferoxamine would theoretically be counterproductive since iron and manganese tend to compete for ligands, and iron sequestration might leave more ion transporters available for manganese uptake. In vitro studies demonstrate increased rates of cellular apoptosis after coincubation with manganese and deferoxamine compared to incubation with manganese alone.⁷²

SUMMARY

- Accumulation of manganese in the brain produces a characteristic neurologic disorder, manganism, with cognitive, psychiatric, and movement abnormalities.
- The movement disorder has many parkinsonian features, including bradykinesia, rigidity, postural instability, gait abnormalities, and hypophonia, but it does not typically respond to levodopa therapy.
- An increased signal in the globus pallidus on T1-weighted MRI is typically but not invariably seen.
- Elevated whole blood manganese concentrations may also help differentiate the cause, but rapid clearance of manganese from the blood makes this a less sensitive test in cases where exposure is remote from the onset of symptoms.
- Treatment is primarily supportive because no chelation regimen has been shown to alter the clinical course.

98 MERCURY

Young-Jin Sue

Mercury (Hg)		
Atomic number	=	80
Atomic weight	=	200.59 Da
Normal concentrations		
Whole blood	<	10 µg/L (50 nmol/L)
Urine	<	20 µg/L (100 nmol/L)

HISTORY AND EPIDEMIOLOGY

Mercury is a metal that is widely toxic to multiple organ systems. Its toxicologic manifestations are well known as a result of thousands of years of medicinal applications, industrial use, and environmental disasters.^{57,91} Mercury occurs naturally in small amounts as the elemental silver-colored liquid (quicksilver); as inorganic compounds such as mercuric sulfide (cinnabar), mercurous chloride (calomel), mercuric chloride (corrosive sublimate), and mercuric oxide; and as organic compounds (methylmercury and dimethylmercury). In recent centuries, mercury-containing preparations were widely used to treat both syphilis and constipation. The musician Paganini was one of several famous persons whose gingivitis, dental decay, ptyalism (excessive salivation), and erethism (pathologic shyness) were attributed to mercury therapy.⁶⁵ In the 1800s, the United States witnessed an epidemic of “hatters’ shakes” or “Danbury shakes” and “mercurial salivation” in hat industry workers.⁹⁹ Danbury, CT, was a US center of felt hat manufacturing in which mercuric nitrate was used to mat animal furs to make felt.^{91,99}

In the early 1900s, acrodynia, or “pink disease,” was described in children who received calomel for ascariasis or teething discomfort.¹² Vividly described in a series of 41 children, the development of acrodynia was more common in younger children, did not seem to correlate with mercury dose, and was not necessarily related to urine concentrations of mercury.⁹⁸

One of the most devastating epidemics of mercury poisoning occurred as the result of a decade of contamination of Minamata Bay in Japan by a nearby vinyl chloride plant during the 1940s. Methylmercury accumulated in the bay’s marine life and poisoned the inhabitants of the local fishing community. Although officially only 121 victims were reported, thousands more are believed to have been affected by what has subsequently been named Minamata disease.^{71,92} The largest outbreak of methylmercury poisoning to date occurred in Iraq in late 1971. Approximately 95,000 tons of seed grain intended for planting and treated with methylmercury as a fungicide were baked into bread for direct consumption, resulting in widespread neurologic symptoms, 6530 hospital admissions, and more than 400 deaths.^{5,18,77}

In 1990, the US Environmental Protection Agency (EPA) banned mercury-containing compounds from interior paints.³ However, mercury-containing paints manufactured before that ruling may still be on interior walls, and mercury-containing paint can still be sold for outdoor use. In 1997, a scientist succumbed to delayed, progressive neurologic deterioration after a minute dermal exposure to dimethylmercury.⁶³

Contemporary exposures occur in the form of mercury-tainted seafood and mercury-based preservatives (thimerosal). However, a once widely feared source of potential poisoning, mercury-containing dental amalgam, does not result in clinically important poisoning. Occasionally, exposure to mercury from broken thermometers leads to poisoning in the home.

The recent movement to replace incandescent light bulbs with compact fluorescent bulbs has once again raised the concern of exposure to mercury in the home and environment. Promoted to reduce greenhouse gas emissions, each bulb contains about 4 mg of elemental mercury.²

Table 98–1 lists some potential sources of mercury exposure.

TABLE 98–1. Exposures to Mercury

	<i>Elemental</i>	<i>Inorganic</i>	<i>Organic</i>
Manufacturing/ Industrial	Barometers	Batteries	Agriculture

FORMS OF MERCURY AND TOXICOKINETICS

The three clinically important forms of mercury—elemental, inorganic, and organic—differ with respect to their toxicodynamics and toxicokinetics (Table 98–2). Each produces distinct clinical patterns of poisoning stemming in part from their unique kinetic features (Table 98–3). For each form, the specific manifestations are determined by the route of exposure, rate of exposure, distribution, biotransformation of mercury within the body, and relative accumulation or elimination of mercury by the target organ systems. Whereas elemental mercury produces pulmonary toxicity, inorganic mercury initially causes gastrointestinal (GI) symptoms followed by nephrotoxicity. A nearly pure neurologic toxicity results from organic (methylmercury) exposure.

TABLE 98–2. Classes of Mercury Compounds

	<i>Chemical Formula</i>	<i>Example</i>
Elemental	Hg ⁰	Quicksilver
Inorganic	Hg ⁺	Mercurous ion
	HgCl	Calomel, mercurous chloride
	Hg ²⁺	Mercuric ion
	HgCl ₂	Mercuric chloride
Organic	Short-chain alkyl–mercury compounds	Methylmercury Ethylmercury Dimethylmercury
	Long-chain mercury compounds	Methoxyethylmercury
	Aryl mercury compounds	Phenylmercury

TABLE 98–3. Differential Characteristics of Mercury Exposure

	<i>Elemental</i>	<i>Inorganic</i>	<i>Organic</i>
Primary route of exposure	Inhalation	Oral	Oral
Primary tissue distribution	CNS, kidney	Blood (transient, acute) Kidney CNS (delayed)	CNS, kidney, liver, blood, hair
Clearance	Renal, GI	Renal, GI	Methyl: GI Aryl: renal, GI
<i>Clinical effects</i>			
CNS	Tremor	Tremor, erethism	Paresthesias, ataxia, tremor, tunnel vision, dysarthria
Pulmonary	+++	–	–
Gastrointestinal	+	+++ (caustic)	+
Renal	+	+++ (ATN)	+
Acrodynia	+	++	–
Therapy	BAL, DMSA	BAL, DMSA	DMSA (early)

ATN = acute tubular necrosis; BAL = British anti-Lewisite; CNS = central nervous system; DMSA = dimercaptosuccinic acid; GI = gastrointestinal.

ABSORPTION

Elemental Mercury

Elemental mercury (Hg^0) is absorbed primarily via inhalation of vapor, although slow absorption after aspiration, subcutaneous deposition, and direct intravenous (IV) embolization occurs.^{48,60,97} Volatility, moderate at room temperature, increases significantly with heating or aerosolization, both of which occur with vacuuming.^{34,83} When inhaled by human volunteers, 75% to 80% of mercury vapor is absorbed.³⁴ However, elemental mercury is negligibly absorbed from an anatomically and functionally normal GI tract, and it is usually considered nontoxic when ingested. Abnormal GI motility prolongs mucosal exposure to elemental mercury and massive ingestion increases subsequent ionization to more readily absorbed forms. Similarly, anatomic GI abnormalities such as fistulae or perforation may be associated with extravasation of mercury into the peritoneal space where elemental mercury is oxidized to more readily absorbed inorganic forms.

Inorganic Mercury

The principal route of absorption for inorganic mercury is the GI tract. Approximately 10% of soluble divalent mercuric salts such as mercuric chloride (HgCl_2) are absorbed following ingestion and dissociation.⁵⁴ Absorption of a relatively insoluble monovalent mercurous compound, such as mercurous chloride (calomel; HgCl), is dependent on its oxidation to the divalent form.⁶⁴ Inorganic mercury is also absorbed across the skin and mucous membranes, as evidenced by urinary excretion of mercury after dermal application of mercurial ointments and powders containing HgCl .⁹⁸ The degree of dermal absorption varies by the concentration of mercury, skin integrity, and lipid solubility of the vehicle. With substantial dermal exposures to mercury salts, skin absorption may be difficult to distinguish from concomitant absorption via other routes, such as ingestion.

Organic Mercury

As in the case of inorganic mercury, organic mercury is primarily absorbed from the GI tract. Methylmercury, considered the prototype of the short-chain alkyl compounds, is approximately 90% absorbed from the gut. Aryl and long-chain alkyl compounds have more than 50% GI absorption.⁶⁴ Although both dermal and inhalational absorption of organic mercury is reported, precise quantitation and exclusion of concomitant absorption by ingestion are difficult to determine.

DISTRIBUTION AND BIOTRANSFORMATION

After absorption, mercury distributes widely to all tissues, predominantly the kidneys, liver, spleen, and central nervous

system (CNS). The initial distributive pattern into nervous tissue of elemental and organic mercury differs from that of the inorganic compounds because of their greater lipid solubility.

Elemental Mercury

Although peak concentrations of elemental mercury are delayed in the CNS as compared with other organs (2–3 days vs. 1 day),³⁴ significant accumulation in the CNS may occur after an acute, intense exposure to elemental mercury vapor. Conversion of elemental mercury to the charged mercuric (Hg^{2+}) cation within the CNS favors retention and local accumulation. Because elemental mercury does not covalently bind to other compounds, its toxicity depends on its oxidation initially to the mercurous ion (Hg^+) and then to the mercuric ion (Hg^{2+}) by the enzyme catalase.⁵⁴ Because this oxidation–reduction reaction favors the mercuric cation at steady state, the distribution and late manifestations of metallic mercury toxicity eventually resemble those of inorganic mercury poisoning. Conversely, and to a lesser extent, inorganic mercuric ions are reduced to the elemental state (Hg^0), although the site and mechanism of this reaction are not well understood.⁶⁴

Inorganic Mercury

The greatest concentration of mercuric ions is found in the kidneys, particularly within the renal tubules. At least in animal studies, administration of mercury induces the renal synthesis of metallothionein, a compound that binds to and detoxifies mercuric ions.⁹ Very little mercury is found as free mercuric ions. In blood, mercuric ions are found both within the red blood cells (RBCs) and bound to plasma proteins in approximately equal proportions. Blood concentrations are greatest immediately after inorganic mercury exposure, with rapid waning as distribution to other tissues occurs. Although penetration of the blood–brain barrier is poor because of low lipid solubility, slow elimination and prolonged exposure contribute to consequential CNS accumulation of mercuric ions. Within the CNS, mercuric ions are concentrated in the cerebral and cerebellar cortices. Although inorganic mercurials undergo organification in marine life, as in the Minamata Bay disaster, the importance of this conversion in humans is unknown. Animal studies demonstrate that the placenta functions as an effective barrier to mercuric ions.⁶⁴

Organic Mercury

Once absorbed, aryl (phenyl mercury) and long-chain alkyl mercury compounds differ from the short-chain organic mercury compounds (ie, methylmercury) in an important way—the former possess a labile carbon–mercury bond, which is subsequently cleaved, releasing the inorganic mercuric ion. Thus, the distribution pattern and toxicologic manifestations produced by the aryl and long-chain alkyl compounds beyond the immediate postabsorptive phase are comparable to those of inorganic mercury, but organification has facilitated absorption and reduced the local caustic effects.⁶⁴ By contrast, short-chain alkyl mercury compounds possess relatively stable carbon–mercury bonds that survive the absorptive phase, although conversion to the inorganic mercuric cation at a rate of less than 1% per day may occur after absorption.¹⁰⁰ Because it is lipophilic, methylmercury readily distributes across all tissues, including the blood–brain barrier and placenta.³⁶ An important consequence of this property is the devastating neurologic degeneration that develops in prenatally exposed infants with Minamata disease.

After methylmercury is distributed to brain tissue, its fate is uncertain. Animal evidence indicates that methylmercury is converted to inorganic mercury in brain tissue.⁵¹ Primates fed oral methylmercury daily for periods exceeding one year and then killed within days of the last exposure demonstrated an average brain inorganic mercury fraction of only 19%. By contrast, when the postexposure period was extended to between 150 and 650 days, the inorganic mercury fraction increased to 88%. Similarly, long-term survivors of methylmercury poisoning had a higher ratio of inorganic mercury to total mercury in their brains.²⁴ In one patient who survived 22 years after methylmercury ingestion, autopsy revealed that the level of brain mercury was nearly completely in the inorganic form.

Methylmercury concentrates in RBCs to a much greater degree than do mercuric ions, with an RBC-to-plasma ratio of about 10:1 (in contrast to 1:1 RBC-to-plasma ratio for inorganic mercury).¹⁰⁰ However, despite this apparent affinity for nervous tissue and RBCs, the greatest methylmercury concentrations are found in the kidneys and liver. In addition, because of the extensive sulfhydryl bonds in hair, methylmercury deposits in hair at concentrations approximately 250 times that found in whole blood.⁴⁵

ELIMINATION

Elemental Mercury and Inorganic Mercury

Mercuric ions are excreted through the kidney by both glomerular filtration and tubular secretion and in the GI tract by transfer across gut mesenteric vessels into feces. Small amounts are reduced to elemental mercury vapor and volatilized

from skin and lungs. The total-body half-life of elemental mercury and inorganic mercury is estimated at approximately 30 to 60 days.^{17,54}

Organic Mercury

By contrast to elemental mercury and inorganic mercury, the elimination of short-chain alkyl mercury compounds (such as methyl mercury) is predominantly fecal. Enterohepatic recirculation contributes to its somewhat longer half-life of about 70 days. Less than 10% of methylmercury is excreted in urine and feces as the mercuric cation.¹⁰⁰

PATHOPHYSIOLOGY

The pervasive disruption of normal cell physiology by mercury arises from its avid covalent binding to sulfur, replacing the hydrogen ion in the body's ubiquitous sulfhydryl groups. Mercury also reacts with phosphoryl, carboxyl, and amide groups, resulting in widespread dysfunction of enzymes, transport mechanisms, membranes, and structural proteins.

Because mercury deposits in all tissues, the clinical manifestations of mercury toxicity involve multiple organ systems with variable features and intensity. Necrosis of the GI mucosa and proximal renal tubules, which occurs shortly after mercury salt poisoning, is thought to result from direct oxidative effect of mercuric ions. An immune mechanism is attributed to the membranous glomerulonephritis and acrodynia associated with the use of mercurial ointments.¹⁰

Neurologic manifestations of methylmercury poisoning correlate with pathologic findings in the brains of both adults and children who were prenatally exposed.^{56,92} Grossly, atrophy of the brain is more severe in children who had prenatally or postnatally acquired methylmercury compared with the brains of those exposed as adults. In the adult brain, neuronal necrosis and glial proliferation are most prominent in the calcarine cortex of the cerebrum and in the cerebellar cortex. In fetal Minamata disease, similar lesions are present but in a more diffuse and severe form. Atrophy of the cerebellar hemispheres, postcentral gyri, and calcarine area of the brain demonstrated on magnetic resonance images in organic mercury-poisoned patients correlates with clinical findings of ataxia, sensory neuropathy, and visual field constriction, respectively.⁴⁷ Neuropathologic examination of the brain of a scientist who died after unintentional dermal exposure to dimethylmercury revealed lesions in the cerebellum, temporal lobe, and visual cortex.⁸⁶

In rats, neuronal cytotoxicity of methylmercury may result partly from muscarinic receptor-mediated calcium release from smooth endoplasmic reticulum of cerebellar granule cells.⁵⁰ There is animal evidence that methylmercury may trigger reactive oxygen species production. In addition, methylmercury inhibits astrocyte uptake of cysteine, the rate-limiting step in the production of glutathione, a major antioxidant in mammalian cell systems.⁸⁵ Cultured astrocytes accumulated methylmercury and exhibited increased mitochondrial permeability and oxidative injury.¹⁰¹

CLINICAL MANIFESTATIONS

Elemental Mercury

Symptoms of acute elemental mercury inhalation occur within hours of exposure and consist of cough, chills, fever, and shortness of breath. GI complaints include nausea, vomiting, and diarrhea accompanied by a metallic taste, dysphagia, salivation, weakness, headaches, and visual disturbances. Chest radiography during the acute phase may reveal interstitial pneumonitis and both patchy atelectasis and emphysema. Symptoms may resolve or progress to acute respiratory distress syndrome with respiratory failure and death. Survivors of severe pulmonary toxicity may develop interstitial fibrosis and residual restrictive pulmonary disease. The acute respiratory symptoms may occur concomitantly with or lead to the development of subacute inorganic mercury poisoning manifested by tremor, renal dysfunction, and gingivostomatitis.^{13,44,75} Thrombocytopenia may also occur during the acute phase.³⁰

Although acute exposure to elemental mercury vapor occurs most commonly in the occupational setting, poisonings caused by mishandling of the metal in the home are well reported.^{15,16,40,58,88} In fact, attempts at home metallurgy using metallic mercury have resulted in fatalities with ambient air concentrations of mercury as high as 0.9 mg/m³. The current US Occupational Safety and Health Administration permissible exposure limit for mercury vapor is 0.1 mg/m³ of air as a ceiling limit.⁶⁶

As with other inhaled toxins, children may be more sensitive to the pulmonary toxicity of mercury vapor because of their ratio of minute ventilation to body size.⁵⁸ Although pulmonary toxicity from elemental mercury usually results from inhalation of vapor, massive endobronchial hemorrhage followed by death has occurred secondary to direct aspiration of metallic mercury into the tracheobronchial tree.¹⁰³ Gradual volatilization of elemental mercury results in chronic toxicity from improper handling, such as vacuuming spilled mercury.⁸³

The clinical importance of volatilized metallic mercury from dental amalgams for both the dentist and patient is controversial. The preponderance of evidence refutes the idea that dental amalgam causes mercury poisoning. Several

comprehensive reviews of the subject conclude that (1) occupational exposure to mercury from dental amalgam is acceptably low, provided that recommended preventive measures such as adequate ventilation are adhered to, (2) the quantity of mercury vaporized from dental amalgam by mechanical forces, such as chewing, is clinically insignificant, and (3) only in exceedingly rare cases will immunologic hypersensitivity to mercury amalgam (manifested as cutaneous signs and symptoms and confirmed by patch testing) necessitate removal of the amalgam.^{27–29,49,87}

Unusual cases of chronic toxicity have resulted from intentional subcutaneous or IV injection of elemental mercury (Fig. 5–6 and Fig. 98–1).^{39,60} Aside from management of systemic mercury toxicity, local wound care and excision of deposits of mercury are additional therapeutic challenges presented by these cases. Serial or repeat radiographs are useful in guiding the removal of the radiopaque deposits.

FIGURE 98–1. Anteroposterior (A) and lateral (B) views of the elbow after an unsuccessful suicidal gesture involving an attempted intravenous injection of mercury in the antecubital fossa. Note the extensive subcutaneous mercury deposition, which was partially removed by surgical intervention. (Used with permission of Diane Sauter, MD.)

Inorganic Mercury

Acute ingestion of mercuric salts produces a characteristic spectrum from severe irritant to caustic gastroenteritis. Immediately after the ingestion, a grayish discoloration of mucous membranes and metallic taste may accompany local oropharyngeal pain, nausea, vomiting, and diarrhea followed by abdominal pain, hematemesis, and hematochezia. The lethal dose of mercuric chloride is estimated to be 30 to 50 mg/kg.⁹⁴ The life-threatening manifestations of severe acute mercuric salt ingestion are hemorrhagic gastroenteritis, massive fluid loss resulting in shock, and kidney failure.⁸¹

Oropharyngeal injury, nausea, hematemesis, hematochezia, and abdominal pain were the most prominent symptoms in a series of 54 patients who presented after ingesting up to 4 g of mercuric chloride.⁹⁴ In this series, fatality was associated with the early development of oliguria (within 3 days) likely due in large part to lack of routinely available hemodialysis. The development of anuria appeared to be related to the dose of mercuric chloride ingested. The histopathologic finding of proximal tubular necrosis after mercuric salt poisoning results both from direct toxicity to renal tubules and from renal hypoperfusion caused by shock. Consequently, aggressive fluid therapy to maintain perfusion is useful.⁸²

Acute ingestion of mercuric salts is usually intentional, but unintentional ingestion occurs sporadically in both children and adults.⁴¹ Although ingestion of button batteries containing mercuric oxide is associated with a greater incidence of fragmentation than with other batteries, clinically significant systemic mercury toxicity by this route has not been reported.^{52,55} Mercuric chloride-containing stool preservatives are another potential source of unintentional inorganic mercury poisoning. Ingestion of 10 to 20 mL of a polyvinyl alcohol preservative that contained 4.5% mercuric chloride resulted in bloody gastroenteritis and proteinuria.⁸⁴ Patent³⁹ and Ayurvedic⁸⁰ medicines are also associated with unintentional inorganic mercury poisoning.⁴³ These xenobiotics are not subject to US Food and Drug Administration (FDA) regulation, available without prescription, of variable composition, and are often inadequately labeled (Chap. 45).

Subacute or chronic mercury poisoning occurs after inhalation, aspiration, or injection of elemental mercury; ingestion or application of mercury salts; or ingestion of aryl or long-chain alkyl mercury compounds. Slow in vivo oxidation of elemental mercury and dissociation of the carbon–mercury bond of aryl or long-chain alkyl mercury compounds result in the production of the inorganic mercurous and mercuric ions.

The predominant manifestations of subacute or chronic mercury toxicity include GI symptoms, neurologic abnormalities, and renal dysfunction. GI symptoms consist of a metallic taste and burning sensation in the mouth, loose teeth and gingivostomatitis, hypersalivation (ptyalism), and nausea.⁹⁸ The neurologic manifestations of chronic inorganic mercurialism include tremor, as well as the syndromes of neurasthenia and erethism. Neurasthenia is a symptom complex that includes fatigue, depression, headaches, hypersensitivity to stimuli, psychosomatic complaints, weakness, and loss of concentrating ability. Erethism, derived from the Greek word *erethē*, describes the easy blushing and extreme shyness of affected individuals. Other symptoms of erethism include anxiety, emotional lability, irritability, insomnia, anorexia, weight loss, and delirium. Mercury produces a characteristic central intention tremor (Chap. 24) that is abolished during sleep. In the most severe forms of mercury-associated tremor, choreoathetosis and spasmodic ballismus may be present. Other neurologic manifestations of inorganic mercurialism include a mixed sensorimotor neuropathy, ataxia, concentric constriction of visual fields (“tunnel vision”), and anosmia.

Chronic poisoning with mercuric ions is associated with renal dysfunction, which ranges from asymptomatic, reversible proteinuria to nephrotic syndrome with edema and hypoproteinemia. An idiosyncratic hypersensitivity to mercury ions is thought to be responsible for acrodynia, or “pink disease,” which is an erythematous, edematous, and hyperkeratotic induration of the palms, soles, and face, and a pink papular rash that was first described in a subset of children exposed to mercurous chloride powders.⁹⁸ The rash is described as morbilliform, urticarial, vesicular, and hemorrhagic. This symptom complex also includes excessive sweating, tachycardia, irritability, anorexia, photophobia, insomnia, tremors, paresthesias, decreased deep-tendon reflexes, and weakness. The acral rash may progress to desquamation and ulceration. The prognosis is favorable after withdrawal from mercury exposure. Childhood acrodynia has become uncommon since the abandonment of mercurial teething powders and diaper rinses. Occasional case reports are still noted, however, with fluorescent light bulbs and phenylmercuric acetate–containing paint implicated.^{3,95}

Thimerosal is an example of an aryl mercury compound that results in chronic inorganic mercury toxicity. It is a compound that was widely used as a preservative in the pharmaceutical industry (Chap. 55). Although initial kinetics have suggested a stable ethyl–mercury bond, the later elimination phase more closely resembles that of the inorganic mercury compounds. Thimerosal is approximately 50% mercury by weight. Generally considered safe, toxicity and death can nevertheless occur after both intentional overdose and excessive therapeutic application of merthiolate (0.1% thimerosal or 600 µg/mL mercury).^{70,76}

Concern that the cumulative dose of thimerosal in childhood immunizations may exceed federally recommended maximum mercury doses (EPA, 0.1 µg/kg/d; Agency for Toxic Substances and Disease Registry, 0.3 µg/kg/d; FDA, 0.4 µg/kg/d) led to a call by the American Academy of Pediatrics to reduce or eliminate thimerosal from vaccines.⁴ In particular, controversy exists whether thimerosal causes autism. Although sensitization after use in vaccinations has been reported in atopic children,⁶⁹ clinical mercury toxicity has not been reported in appropriately immunized children. Moreover, many studies suggest that the incidence of autism is unrelated to the use of thimerosal-containing vaccines.^{7,53,68,89} Similarly, no causal association with early thimerosal exposure and adverse neuropsychological outcomes was shown in children tested at 7 to 10 years of age.⁹³ At the present time, there is clearly more evidence for risk to child health from the diseases targeted for prevention by the vaccines than from thimerosal. In 2010, US courts rejected a causal relationship between thimerosal and autism.²⁶

Thimerosal continues to be used in medically underserved nations as a preservative in multidose vials in areas with inadequate refrigeration.³¹ Nevertheless, since 2001, routinely administered childhood vaccines in the United States no longer contain thimerosal.^{4,37}

Organic Mercury Compounds

By contrast to the inorganic mercurials, methylmercury produces an almost purely neurologic disease that is usually permanent except in the mildest of cases. Although the predominant syndrome associated with methylmercury is that of a delayed neurotoxicity, acute GI symptoms, tremor, respiratory distress, and dermatitis may occur.¹⁰⁰ In addition, abnormalities on electrocardiography (ECG; ST segment changes) and renal tubular dysfunction are associated with this poisoning.³⁵

The lipophilic property and slower elimination of methylmercury may contribute to its profound neurologic effects. Characteristically, clinical manifestations occur after the initial poisoning by a latent period of weeks to months. Consequently, the lethal dose of methylmercury is difficult to determine. As noted previously, infants exposed prenatally to methylmercury were the most severely affected individuals in Minamata. Often born to mothers with little or no manifestation of methylmercury toxicity themselves, exposed infants exhibited decreased birth weight and muscle tone, profound developmental delay, seizure disorders, deafness, blindness, and severe spasticity.

The development of neurologic symptoms in infants exclusively breastfed by women exposed to methylmercury after delivery and the detection of mercury in the milk of lactating women implies a risk for mercury poisoning via breast milk.⁴⁶ In one series of lactating women, mercury concentrations in milk were approximately 30% of the concentrations found in blood.⁶⁷ Seven year-old children from the Faroe Islands, who have a diet traditionally high in mercury-containing sea mammals, breast-fed as infants exhibited a diminished benefit (but not deficit) on neuropsychological testing when compared with their counterparts fed formula.³⁸

The rapid decline of blood mercury concentrations in both suckling rats and breastfeeding human infants is attributed to rapid growth of body volume combined with limited transport of mercury by milk.^{62,78,79} Several weeks after methylmercury-contaminated grain was ingested in Iraq, patients began to appear with paresthesias involving the lips, nose, and distal extremities. Symptomatic patients also noted headaches, fatigue, and tremor. More serious cases progressed to ataxia, dysarthria, visual field constriction, and blindness. Other neurologic deficits included hyperreflexia, hearing disturbances, movement disorders, salivation, and dementia. The most severely affected patients lay in a mute, rigid posture punctuated only by spontaneous crying, primitive reflexive movements, or feeding efforts.⁷⁷

Although the outlook for methylmercury neurotoxicity is generally considered dismal, observations over the subsequent 2 years in 49 Iraqi children poisoned during the 1971 outbreak revealed complete resolution or partial improvement in all but the most severely affected.⁵ Of the 40 symptomatic children, 33 mildly to severely affected children showed partial to complete resolution of symptoms, but the seven children classified as “very severely poisoned” remained physically and mentally incapacitated.

An important route of organic mercury exposure is through seafood consumption. The safe level of methylmercury in seafood remains controversial. The FDA action concentration of 1 ppm for methylmercury in fish was set to limit consumption of methylmercury to less than one-tenth of levels found in cases of symptomatic poisoning. The EPA established a reference dose for methylmercury of 0.1 $\mu\text{g}/\text{kg}/\text{d}$.^{72,96} Although elevated blood concentrations (19–53 $\mu\text{g}/\text{L}$) of mercury were found in one group of self-reported high consumers of seafood, increased incidence of cognitive and GI complaints were not.⁴² Even so, concentrations at which fetuses experience adverse effects are unknown. Longitudinal studies of fish-eating populations are conflicting. No effect of a high prenatal fish diet was found on developmental markers in children followed to 17 years of age in the Seychelles Islands.^{22,23}

However, in the studies done in the Faroe Islands and New Zealand, a subtle but significant effect on neuropsychological development was seen.^{20,32,90} In the Faroe Islands, this effect persisted when children were retested at 14 years of age.²⁵ One reason for the discrepancy that occurs between the two populations may be the different patterns of seafood consumption and concentrations of methylmercury in the seafood consumed by each. The Faroese consume low-level mercury containing fish one to three times a week with episodic feasts of highly contaminated pilot whale, whereas the Seychellois consume a more steady diet of low-level contaminated fish on average 12 times per week. The pilot whales consumed in the Faroe Islands were also contaminated with neurotoxic polychlorinated biphenyls, although these compounds were measured and controlled for as a potential confounding variable. The mean concentration of methylmercury in the whale meat consumed in the Faroe Islands was 1.6 $\mu\text{g}/\text{g}$, and the mean concentration of mercury found in New Zealand shark was 2.2 $\mu\text{g}/\text{g}$. By contrast, the mean methylmercury content of Seychellois fish was 0.3 $\mu\text{g}/\text{g}$.⁶¹ The threshold concentration for neuropsychological effects may lie between these concentrations.

No increase in cardiovascular disease risk was seen with mercury exposure in a large cohort of US adults.⁵⁹

The FDA recommends that at-risk populations (ie, pregnant women and women who may become pregnant, nursing mothers, and young children) avoid large predator fish (eg, shark, swordfish, tilefish, and king mackerel) that contain concentrations of methylmercury approaching 1 ppm (1 $\mu\text{g}/\text{g}$). The 2004 FDA/EPA consumer advisory emphasizes the health benefits of eating fish and allow for up to 12 ounces per week of fish and shellfish lower in mercury such as shrimp, canned light tuna, salmon, pollock and catfish and up to 6 ounces of albacore tuna per week. Given the beneficial effects of seafood, efforts should be aimed at decreasing anthropogenic release of mercury rather than elimination of dietary exposure.⁷³

Although methylmercury has greater importance worldwide, the extreme toxicity of another organic mercurial, dimethylmercury, was tragically demonstrated by the delayed fatal neurotoxicity that developed in a chemist who inadvertently spilled dimethylmercury on a break in the gloves on her hands.⁶³ Over a period of several days, she developed progressive difficulty with speech, vision, and gait. Despite chelation and exchange transfusion, she died of mercury neurotoxicity within several months of the exposure.

DIAGNOSTIC TESTING

The dual findings of unexplained neuropsychiatric and renal abnormalities in an individual should alert the clinician to the possibility of mercurialism, as should an at-risk occupation or access by the patient to a mercurial product (Table 98–1). Occupational or environmental exposure and a consistent clinical scenario may be suggestive of mercury poisoning, but

demonstration of mercury in blood, urine, or tissues is necessary for confirmation of exposure. Of the many methods available to measure mercury, cold atomic absorption spectrometry is rapid, sensitive, and accurate but cannot distinguish the various forms of mercury. Thin-layer and gas chromatographic techniques can be used to distinguish organic from inorganic mercury. Whole blood should be collected into a trace element collection tube obtained from the laboratory performing the assay. Urine should be collected for 24 hours into an acid-washed container obtained from a laboratory. Spot collections must be adjusted for creatinine concentration. Attempts to measure or otherwise handle the specimen should be avoided to prevent external contamination (Table 98–4).

TABLE 98–4. Diagnostic Testing for Mercury

	<i>Whole Blood</i>	<i>24-hour Urine</i>	<i>Hair</i>	<i>Clinical</i>
Elemental/ Inorganic	(+) Acute, transient	(++) Confirm exposure Monitor chelation Poor correlation to TBB	(+) Reflects past exposure and external adsorption	(+) Poor correlation to TBB Early detection
Organic	(++) Best reflects TBB	(–) Fecal elimination	(+) Reflects past exposure and external adsorption	(+) Poor correlation to TBB Reflects irreversible CNS toxicity Early detection

CNS = central nervous system; TBB = total body burden.

There is considerable overlap among concentrations of mercury found in the normal population, asymptomatic exposed individuals, and patients with clinical evidence of poisoning. There is no definitive correlation between either whole blood or urine mercury concentration and mercury toxicity. However, mercury serves no useful role in human physiology, and concentrations of 1.0 µg/L or less for whole blood and 0.5 µg/L for urine are generally considered to reflect background exposure in nonpoisoned individuals.¹⁶

For inorganic mercury poisoning, urine mercury concentrations may correlate roughly with exposure severity and neuropsychiatric symptoms,⁷⁴ but the relationship to total-body burden is probably poor. Urine mercury determinations have their greatest usefulness in confirming exposure and monitoring the efficacy of chelation therapy. Whole-blood mercury concentrations may reflect intense, acute inorganic mercury exposure but become less reliable as redistribution to tissues takes place.

Because organic mercury is eliminated via the fecal route, urine mercury concentrations are not useful in methylmercury poisoning. Because methylmercury concentrates in RBCs, the total-body methylmercury burden is best reflected acutely by whole blood concentrations. As methylmercury distributes to and accumulates in brain, the severity of clinical manifestations probably more closely reflects the degree of the irreversible neuronal destruction that has taken place rather than the current body burden of mercury. Correlation of increasing whole-blood mercury concentrations with prevalence of paresthesias was suggested in a population of Iraqis studied early in the course of methylmercury poisoning.¹⁹ However, in another group of patients, whole-blood concentrations did not correlate with severity of methylmercury poisoning.⁷⁷ This apparent discrepancy may have resulted from the finding that paresthesias are among the earliest reported symptoms of methylmercury poisoning.

Because mercury accumulates in the hair, hair analysis has been used as a tool for measuring mercury burden. However, because metal incorporation reflects past exposure and hair avidly binds to noningested environmental mercury, the reliability of this method is questionable and is not recommended. In addition to mercury assays, neuropsychiatric testing, nerve conduction studies, and urine assays for N-acetyl-β-D-glucosaminidase and β₂-microglobulin are advocated for early detection of subclinical inorganic and organic mercury toxicity.^{28,35,74}

GENERAL MANAGEMENT

After the initial assessment and stabilization, the early toxicologic management of a patient with mercury poisoning includes termination of exposure by removal from vapors, washing exposed skin, GI decontamination, supportive measures (eg, hydration, humidified oxygen), baseline diagnostic studies (eg, complete blood count, serum chemistries, venous blood gas, radiography, ECG), specific analysis of whole blood and urine for mercury, consideration of possible cointoxicants, and meticulous monitoring.

Elemental Mercury

Inhalation of mercury vapors or aspiration of metallic mercury may result in life-threatening respiratory failure; in this situation, stabilization of cardiorespiratory function is the initial priority. Postural drainage and endotracheal suction may be effective in removing aspirated metallic mercury. Parenteral deposition of subcutaneous or intramuscular (IM) mercury may be amenable to surgical excision, if well localized (Fig. 98–1).

An adjunct to the initial management of patients with mercury poisoning is consideration for environmental decontamination. Elemental mercury that spills onto solid surfaces should be adsorbed to sand and the resulting mixture then swept into tightly sealed containers. Ideally, a mercury decontamination kit should be used. The kit consists of calcium polysulfide, which contains excess sulfur to convert mercury to water-insoluble mercuric sulfide. Absorbent surfaces, such as carpets, should be removed. Spilled mercury compounds should not be vacuumed because vacuuming could volatilize the mercury.¹⁴ Broken CFL bulbs should be handled and disposed of according to EPA guidelines and local requirements.²

Recommendations for decontamination after breakage include opening windows to release vapor, using adhesive tape to pick up visible fragments, and discarding contaminated material in double-wrapped bags. Guidance for decontamination of major spills and disposal of materials can be provided by local and federal hazardous materials agencies.

Inorganic Mercury

Ingestion of inorganic mercuric may lead to cardiovascular collapse caused by severe gastroenteritis and third-space fluid loss. Fluid resuscitation is a priority. GI decontamination of ingested inorganic mercury is particularly problematic because of its causticity and risk for perforating injury. Nevertheless, one series of patients with mercuric chloride ingestion of up to 4 g reported recovery without long-term GI sequelae in patients who did not succumb to kidney failure.⁹⁴ Therefore, unless there is high suspicion for penetrating GI mucosal injury, removal of mercury from absorptive surfaces should take priority over endoscopic evaluation. The prominence of vomiting makes gastric lavage unnecessary for most patients with inorganic mercury poisoning.

Metals are among the substances that are often considered to be poorly adsorbed to activated charcoal. Nevertheless, the serious nature of late sequelae after mercury absorption, the typically small quantities of mercury ingested, and evidence that inorganic mercuric salts actually have substantial adsorption to activated charcoal (800 mg mercuric chloride can be adsorbed to 1 g activated charcoal) justify the routine administration of activated charcoal.⁶ Whole-bowel irrigation with polyethylene glycol solution may also be useful in removing residual mercury and should be considered, with its progress followed with serial radiographs.

Organic Mercury

Organic mercury exposures do not typically present as single acute ingestions but rather as chronic or subacute ingestion of contaminated food. Therefore, GI decontamination is generally moot with respect to organic mercury poisoning. Nevertheless, its irreversible toxicity coupled with unsatisfactory treatments calls for aggressive decontamination when acute ingestions or dermal exposures occur.

CHELATION

After initial stabilization and decontamination, early institution of chelators may minimize or prevent the widespread effects of poisoning. A high degree of protein binding and distribution to the brain are responsible for the lack of efficacy of other measures to increase mercury clearance, such as peritoneal dialysis and hemodialysis.⁸¹ In one report of the use of continuous venovenous hemodiafiltration in combination with a chelator in a patient with severe inorganic mercury poisoning, 12.7% of the ingested dose was recovered in the ultrafiltrate.²¹ Hemodialysis may nevertheless ultimately be necessary because of the acute kidney failure that often occurs after mercuric chloride poisoning.

Chelators have thiol groups that compete with endogenous sulfhydryl groups for the binding of mercury, thereby preventing inactivation of sulfhydryl-containing enzymes and other essential proteins (Antidotes in Depth: A25 and A26). A history of significant mercury exposure combined with the presence of typical symptoms of mercury poisoning is an appropriate indication for the institution of chelation therapy. Elevated whole-blood and urine mercury concentrations may help support the decision to begin chelation therapy in unclear cases and may also be used to guide the duration of therapy.

Provocative chelation, in which urinary mercury excretion before and after a chelating dose is compared to determine the degree of mercury poisoning, is of no value.⁴² Chelation tends to increase urinary elimination of mercury, regardless of exposure history and baseline excretion.

Elemental Mercury and Inorganic Mercury Salts

For symptomatic acute inorganic mercury poisoning, dimercaprol (BAL) should be administered for 10 days in decreasing dosages of 5 mg/kg/dose every 4 hours IM for 48 hours, then 2.5 mg/kg every 6 hours for 48 hours, followed by 2.5 mg/kg every 12 hours for 7 days. This dosing regimen of BAL, derived from the use of BAL in lead poisoning, may be adjusted according to clinical response and the occurrence of adverse reactions.

When a patient can take oral medications, BAL therapy may be replaced with succimer (2,3-dimercaptosuccinic acid) at 10 mg/kg orally three times a day for 5 days, then twice a day for 14 days if the GI tract is clear. Because headache, nausea, vomiting, abdominal pain, and diaphoresis may result from BAL chelation therapy, oral succimer is recommended in patients who are not acutely ill or who have been chronically poisoned.

Either BAL or succimer is considered the treatment of choice for inorganic mercury poisoning in the United States, but a few other chelators deserve mention. 2,3-Dimercapto-1-propanesulphonate (DMPS) is a water-soluble dimercaprol derivative that is used in Europe. It may be administered both IV and orally. D-Penicillamine is an orally administered monothiol. Its adverse events—GI distress, rashes, leukopenia, thrombocytopenia, and proteinuria—although uncommon in therapeutic doses, seriously limit the usefulness of the drug. N-acetyl-D,L-penicillamine (NAP), an investigational analog of D-penicillamine, is thought to be a more effective chelator of mercury than is D-penicillamine, perhaps because of its greater stability.^{8,33}

Organic Mercury Compounds

The neurotoxicity of methylmercury and other organic mercury compounds is resistant to treatment, and therapeutic options are less than satisfactory. In rats, both BAL and D-penicillamine effectively reduced tissue mercury and prevented neurologic toxicity if administered within the first day of a methylmercury injection.¹⁰² Neither treatment reversed neurologic toxicity when administered 12 days after methylmercury injection. DMPS, D-penicillamine, NAP, and a thiolated resin all led to a marked reduction of blood half-life of mercury (ie, 10, 24, 23, and 19 days, respectively, vs. 60 days) during the outbreak of methylmercury poisoning in Iraq in 1971.¹⁹ Clinical improvement was not observed in any treatment group, but it is reasonable to postulate that reducing the total-body burden of methylmercury may prevent or limit the progression of disease. When studied in mice poisoned with methylmercury,¹ succimer was superior to NAP, DMPS, and a thiolated resin in decreasing brain mercury and increasing urinary excretion. Brain mercury was decreased to 35% of control, and the total-body burden fell to 19%. Some animal evidence suggests that BAL may increase mercury mobilization into the brain.¹¹ For this reason and the lack of serious GI symptoms necessitating parenteral chelation, BAL should not be used for the treatment of patients with organic mercury poisoning.

Because the neurologic impairment associated with methylmercury is both profound and essentially irreversible, early recognition of poisoning and prevention of neurotoxicity are essential to a successful outcome. Although further investigation is necessary, succimer may prove to be the treatment of choice for methylmercury poisoning because of its apparently low toxicity and reported efficacy in animal trials.

SUMMARY

- Mercury poisoning by any of the three major forms—elemental, inorganic, and organic—presents a complex toxicologic problem associated with a large variety of clinical presentations.
- An ever-present awareness of the problems coupled with the knowledge of the differing clinical forms is essential for both early recognition and effective treatment.
- Although some chelators do show promise in the treatment of mercury poisoning, neurologic sequelae, particularly those resulting from organic mercury exposures, remain largely irreversible.
- Promotion of public education regarding the dangers of mercury, its avoidance, and proper disposal may aid in the prevention of mercury poisoning.

99 NICKEL

John A. Curtis and David A. Haggerty

Nickel (Ni)	
Atomic number	= 28
Atomic weight	= 58.7 Da
Normal concentrations	
Serum	< 1 µg/L (17 nmol/L)
Urine	< 6 µg/L (100 nmol/L)

HISTORY AND EPIDEMIOLOGY

Nickel is a ubiquitous metal commonly found in both home and industry. It exists in a variety of chemical forms, from naturally occurring ores to synthetically produced nickel carbonyl. Elemental nickel is a white, lustrous metal whose name is derived from the German word “kupfernickel” or “devil’s copper.” Swedish chemist Baron Axel Fredrik first identified nickel in 1751 in a mineral known as niccolite. Nickel comprises 0.008% of the Earth’s crust and is found in diverse locations, ranging from meteorites and soil to bodies of fresh and saltwater.

First produced by the Chinese, nickel has been used as a component in a variety of metal alloys for more than 1700 years. The first malleable nickel was produced by Joseph Wharton following the American Civil War. Wharton went on to sell bulk quantities of nickel to the US government for the minting of 3-cent coins, and later donated the equivalent of 3.3 million of these coins to help fund what is today known as the Wharton School of Business.⁶⁵ The modern US 5-cent piece, the “nickel,” is actually only approximately 25% nickel by weight, and all US coins except the penny are made of nickel-containing alloys.¹⁰

Nickel ores typically consist of accumulations of nickel sulfide minerals of relatively low nickel content. Although a variety of technical methods for extracting nickel from ore have been developed, one method of special note was developed in 1890 by Ludwig Mond, who is credited with the discovery of nickel carbonyl. The Mond process for the extraction of nickel involves passing carbon monoxide over smelted ore. This creates nickel carbonyl, which then decomposes at high temperatures to produce purified nickel and carbon monoxide.⁶⁵ Nickel mining ceased 30 years ago in the United States, and despite an increasing worldwide demand, as of 2011 there were still no active domestic nickel mines.¹⁰ Nickel is imported into the United States from other nickel-rich countries, such as Canada, Russia, and Australia, while domestic production of nickel in the United States is essentially limited to the recycling of nickel-containing metals.

Nickel is a siderophoric material that forms naturally occurring alloys with iron, a property that has made it useful for many centuries in the production of coins, tools, and weapons. Today, most nickel is used in the production of stainless steel, a highly corrosion-resistant alloy containing 8% to 15% nickel by weight.

Occupational exposure to nickel and nickel containing compounds occurs in a variety of industries, including nickel mining, refining, reclaiming, and smelting. Chemists, magnet makers, jewelry makers, oil hydrogenator workers, battery manufacturers, petroleum refinery workers, electroplaters, stainless steel and alloy workers, and welders are at increased risk for exposure to nickel and nickel-containing compounds. Most nonindustrial human exposures to nickel are usually from dietary and environmental sources, although cigarette smoking is an important nickel exposure and elevates urinary nickel concentrations.⁶³ In the occupational setting, nickel carbonyl is responsible for the great majority of acute nickel toxicity, while in clinical practice, the most common health issue related to nickel is the development of allergic dermatitis from jewelry and clothing, as well as cosmetics and complementary and alternative medicines.^{9,19} Nickel and Toxicodendron species exposures are the most common causes of allergic contact dermatitis, with a large proportion of the population—particularly women—demonstrating nickel sensitivity.

TOXICOKINETICS

Exposure

Nickel occurs naturally in soil, volcanic dust, and fresh and saltwater, but it also enters the environment from the combustion of fuel oil, municipal incineration, nickel refining processes, and the production of steel and other nickel alloys that may allow aerosolized nickel to be disseminated into the environment.

The specific form of nickel emitted to the atmosphere depends on the source. Complex nickel oxides, nickel sulfate, and metallic nickel are associated with combustion and incineration, as well as smelting and refining processes. Consequently, ambient air concentrations of these forms of nickel tend to be higher in urban areas, and concentrations of nickel in urban household dust may be elevated under certain circumstances and thus may pose some variable exposure risk for young children who crawl or sit on floors.

Nickel carbonyl, $\text{Ni}(\text{CO})_4$, deserves special mention. This highly volatile and potentially dangerous liquid nickel compound is a product of the reaction of nickel and carbon monoxide and is commonly used in nickel refining and petroleum processing, and as a chemical reagent. Its high vapor pressure and high lipid solubility lead to rapid systemic absorption through the lungs. In the air and in the body, it decomposes into metallic nickel and carbon monoxide and its toxicity has been compared with hydrogen cyanide.³⁵ Workers exposed to nickel carbonyl are commonly screened for low level exposure, but disasters such as the Gulf Oil Company refinery incident in 1953, and the Toa Gosei Chemical company incident in 1969, resulted in hundreds of inhalational exposures.⁶⁵

However, non-occupational exposures to nickel are typically environmental and dietary. Ambient air nickel concentrations are typically around 10 ng/m^3 , while soil usually has nickel concentrations of 4 to 80 ppm, with some areas much higher. Concentrations of metallic nickel in drinking water in the United States are generally below $20 \text{ }\mu\text{g/L}$, but elevated concentrations of nickel in household and other potable and nonpotable water sources may result from corrosion and leaching of nickel alloys present in various plumbing fixtures, including valves and faucets.²² Although many water suppliers in the United States monitor nickel concentrations in their water, there is currently no US Environmental Protection Agency (EPA) regulation regarding how much nickel is permissible in drinking water.

Dietary intake is a recognized source of nickel exposure for humans. Foods high in nickel include nuts, legumes, cereals, licorice, and chocolate. In addition, certain homeopathic medications, ginseng products, Indian herbal teas, Nigerian herbal remedies, and Chinese herbal plants are high in nickel content, with some Nigerian herbal remedies reportedly containing up to $78 \text{ mg nickel/g substance}$.¹⁹ Nickel is not considered an essential element for human health and dietary recommendations for nickel have not been established. Normal consumption is between 0.3 to 0.6 mg per day, with the majority of this being unabsorbed by the gastrointestinal tract. A Danish meta analysis of 17 studies suggested that up to 1% of individuals may develop allergic contact dermatitis at the low level of oral nickel exposure represented by dietary and drinking water sources.³⁰ Although estimates vary widely, the total body burden for a 70-kg reference human is about 10 mg of nickel, giving an average body concentration of 0.1 ppm.²² No clear biologic function has been determined for nickel in humans, but it may serve as a cofactor for various enzymes.

Absorption

Nickel may enter the body through the skin, lungs, and gastrointestinal tract. The amount and rate of absorption is dependent on the water solubility of the nickel compound. Once in the body, nickel exists primarily as the divalent cation (Ni^{2+}). Independent of the particular nickel compound involved in the exposure, it is nickel ion (Ni^{2+}) that is typically measured in the serum or urine.

Following inhalational exposure, nickel accumulates in the lungs, but only 20% to 35% of nickel deposited in the human lung is systemically absorbed.²² The remainder of the inhaled material is swallowed, expectorated, or deposited in the upper respiratory tract. Subsequent systemic absorption from the respiratory tract is dependent on the solubility of the specific nickel compound in question. Soluble nickel salts (nickel sulfate and nickel chloride) are more easily absorbed, whereas the less-soluble oxides and sulfides of nickel are absorbed to a lesser extent.

Because water-soluble nickel compounds tend to be more readily absorbed from the respiratory tract when compared with poorly soluble nickel compounds, exposure to the soluble nickel chloride or nickel sulfate results in higher urinary nickel concentrations than does exposure to less-soluble nickel oxide or nickel subsulfide, while the less soluble compounds may have a longer apparent half-life. This likely at least partially represents a longer absorption phase.

The gastrointestinal absorption of nickel compounds varies with the particular nickel compound as well as coingestants. For example, approximately 27% of the total nickel in nickel sulfate given to humans in drinking water is absorbed, whereas only approximately 1% is absorbed when given in food. Serum nickel concentrations peak between 1.5 and 3 hours following ingestion.⁶⁸ The presence of food in the gastrointestinal tract appears to reduce the absorption of nickel, and most ingested nickel remains in the gut and is excreted in the feces.

While systemic absorption of nickel can occur through skin contact, much of the applied nickel remains in the keratinized skin, with limited absorption by keratinocytes.³⁷

Distribution

In human serum, the exchangeable pool of primarily divalent nickel is bound to albumin, L-histidine, and α 2-macroglobulin.⁴⁷ A nonexchangeable pool of nickel that is tightly bound to a transport protein known as nickeloplasmin also exists in the serum. Nickel crosses the placenta and is present in breast milk.

Nickel is also concentrated in various solid organs. An autopsy study of individuals not occupationally exposed to nickel reported the highest concentrations of nickel in the lungs, followed by the thyroid, adrenals, kidneys, heart, liver, brain, spleen, and pancreas.⁵¹ Nickel concentrations in the nasal mucosa are higher in workers exposed to less-soluble nickel compounds relative to soluble nickel compounds,⁷⁵ indicating that, following inhalation exposure, less-soluble nickel compounds remain deposited on the nasal mucosa.

Elimination

In humans, most ingested nickel is excreted in the feces; however, because more than 90% of ingested nickel does not leave the gut,⁶⁶ most of the nickel found in feces represents the unabsorbed fraction rather than the elimination of body nickel.⁶⁸ Absorbed nickel is primarily excreted in the urine and, to a lesser degree, other bodily fluids.

Regardless of the route of exposure, workers occupationally exposed to nickel have increased urinary concentrations of nickel.^{4,26} Animal studies indicate that nickel oxide, an insoluble compound, is slowly eliminated from the lungs via macrophages and excreted in feces, while more soluble compounds, such as nickel subsulfide, were excreted primarily in the urine.⁷

In nickel workers, urinary excretion increased from the beginning to the end of the shift, indicating that a fraction of absorbed nickel is rapidly eliminated.^{23,75} Similarly, urinary excretion increased as the work week progressed, indicating the presence of a fraction that is excreted more slowly. In fact, after a massive inhalational welding exposure, the half-life of nickel in urine and blood followed a biphasic exponential decay pattern of excretion, and was 25 and 610 days in urine, and 30 and 240 days in blood, indicating potential saturation of elimination pathways and delayed absorption and/or redistribution of nickel.⁵⁵

Studies of workers who unintentionally ingested water contaminated with nickel sulfate and nickel chloride reported a mean serum half-life of nickel was 60 hours, but was reportedly decreased substantially (≤ 27 hours) when the workers were treated with intravenous fluids.⁶⁷

The available literature supports the view that systemically absorbed nickel is excreted through the kidneys, with some excretion of insoluble compounds in the feces. Due to the previously mentioned factors affecting absorption, the apparent half-life following exposure may reflect continuing absorption and will therefore depend on the route of exposure and the particular nickel species involved.

CLINICAL MANIFESTATIONS

Acute

The clinical manifestations associated with acute exposure to nickel depend on the particular compound and route of exposure. Inhalation of nickel-containing aerosolized particles tends to affect the lungs and upper airways directly, whereas ingestion and intravenous administration may result in systemic toxicity, usually involving the nervous system (Table 99–1).

TABLE 99–1. Sequelae Associated with Nickel Carbonyl Poisoning

Acute respiratory distress syndrome/interstitial pneumonitis
Myocarditis
Altered mental status
Seizures
Profound weakness (sometimes requiring ventilatory support)
Prolonged neurasthenic syndrome (up to 6 months postexposure)
Death (secondary to interstitial pneumonitis or cerebral edema)

The most common disorder associated with exposure to nickel, by far, is an allergic dermatitis. Although acute toxicity

has been reported following various routes of exposure, the most important source of acute nickel toxicity is inhalational exposure to nickel carbonyl, which is associated with pulmonary, neurologic, and hepatic dysfunction.⁶⁵

Nickel Allergy and Dermatitis. Nickel dermatitis was first reported in the late 1800s in nickel-plating workers and was recognized as an allergic reaction in 1925. Since then, nickel has been recognized as a common cause of allergic contact dermatitis. Ni²⁺ is not itself antigenic but acts as a hapten, binding larger proteins and inducing conformational changes such that these become recognized as non-self-antigens.²⁸

The allergic reaction caused by contact with nickel is a type IV delayed hypersensitivity immune response that typically occurs in two phases. In the first phase, sensitization occurs when nickel enters the body. The second phase occurs when the body is re-exposed to nickel, at which time allergy manifests. The diagnosis of nickel allergy is suggested by specific historical findings listed in [Table 99–2](#).

TABLE 99–2. Findings Suggestive of Nickel Dermatitis

Previous history of allergic response to jewelry

Multiple body piercings

Eruptions at the site of metal contact, or flexor areas, if generalized

Eruptions following placement of orthodontic appliances containing high concentrations of nickel (unusual)

Seasonal dermatitis in warm months (increased metal–skin contact and increased sweating)

Facial dermatitis in mobile phone users

One population survey reported that 3% of men and 15% of women demonstrated evidence of allergy to nickel.⁴² More recent studies report even higher prevalences, ranging between 15% and 25%.³⁸ The fivefold greater prevalence of nickel allergy in women is presumably a consequence of their higher rates of body piercing and more frequent wearing of jewelry, both of which are risk factors for nickel sensitization. It is unclear if European nickel regulations have succeeded in reducing rates of nickel sensitivity although this has been suggested by several studies.⁷⁴

Nickel dermatitis is classified into two types: primary and secondary. The more common primary dermatitis presents as a typical eczematous reaction in the area of skin that is in contact with nickel. It is characterized initially by erythematous papules that may proceed to lichenification due to pruritus and scratching. These eruptions may mimic basal cell carcinoma.²⁵ Areas typically involved are the wrists, as a result of wearing watches and bracelets, the ears from earrings, and the periumbilical area at the site of contact with jewelry, nickel-containing buttons on jeans or nickel-containing belt buckles ([Fig. 99–1](#)). Approximately 50% of all belt buckles and 10% of buttons on blue jeans contain nickel.¹³ The most common cause for nickel dermatitis in women is direct contact from jewelry, garments, wristwatches, cosmetics, and occupational contact in the metal, hairdressing, tailoring, hotel, and restaurant industries. In men, nickel dermatitis is often occupational but may also, in some individuals, be related to jewelry, body piercing, garments, or even metal guitar strings.

Figure 99–1. Nickel dermatitis from jewelry. (Used with permission of Brian Wexler.)

The secondary form involves a more widespread dermatitis as a result of other exposures, such as ingestion or inhalation of nickel compounds, and implantation of metal medical devices, and may be regarded as a systemic contact dermatitis elicited by nickel. Secondary eruptions are typically symmetrically distributed and may localize in the elbow flexure, on the eyelids, on the sides of the neck and face, and can become widespread.

Nickel in foods, excessive skin contact, and certain orthodontic appliances with high nickel content are all linked to this eczematous eruption. Nonetheless, orthodontic exposure to nickel-containing alloys is unlikely to induce hypersensitivity reactions in patients without prior sensitization, and such reactions are still infrequent even in those sensitized.⁴⁹

Other types of medical devices containing nickel have the potential to induce either primary or local nickel dermatitis. Occlusion of a biliary stent attributed to nickel allergy has been reported.³² Much debate has arisen over the past decade regarding metallic coronary stents and the potential for nickel allergy-induced restenosis. Several studies have reported increased restenosis in nickel-allergic patients with bare-metal stainless steel³⁴ and cobalt-chromium² stents, although others have failed to find such a correlation.⁷³ Drug-eluting stents may mitigate any effect of metal allergy on rates of restenosis.⁴⁴

It is reported that the bimetallic core structure of the 1 Euro and 2 Euro coins creates an electrical potential that results in the release of nickel when in contact with sweat. While no general rise in the rate of nickel sensitivity has been confirmed, cases of dermatitis in certain high-risk patients are reported.⁵⁴

Recently, reports have emerged involving cases of contact dermatitis in users of certain types of cellular phones, with testing confirming nickel release in such phones.³⁹ Therefore, nickel should be considered a potential cause in cases of facial contact dermatitis of unknown etiology.

One study showed that following skin application nickel salts are retained in the skin for an extended period of time,³⁶ which could lead to prolonged antigen processing and consequent immune responses in dermal tissue. There may also be a genetic basis for nickel sensitization. Filaggrin gene mutations are reportedly associated with nickel contact dermatitis as a result of breakdown in nickel chelation in the stratum corneum, allowing for greater epidermal absorption of nickel.⁷² Development of an allergy, like most of toxicology, is probably dose and time related, and this is the basis of the recent EU regulations to limit consumer exposure to nickel.

INHALATIONAL EXPOSURE

Nickel Carbonyl

Nickel carbonyl is the most harmful form of nickel and the majority of acute occupational nickel exposures involve nickel carbonyl. Nickel carbonyl is described as having a “musty” or “sooty” odor, although thresholds for detection vary considerably and potentially harmful exposures cannot be excluded simply by a reported lack of odor. Exposure to concentrations less than 100 mg/m³ is fatal in rats after 20 minutes.^{33,69} Once dissociated, nickel carbonyl can be oxidized in tissues to Ni²⁺.

Nickel carbonyl exposure may cause symptoms rapidly or symptoms may be delayed. In a series of 179 exposures, approximately 40% of patients reported symptoms within 1 hour of exposure; however, it is important to note that symptoms were delayed for approximately 1 week in 20% of patients, and even patients with mild initial symptoms could develop severe delayed symptoms, although usually, within the next 2 days.⁵⁸ In patients who developed symptoms shortly following exposure, the initial manifestations involved nonspecific complaints, including respiratory tract irritation, chest pain, cough, dyspnea, frontal headache, dizziness, weakness, and nausea. Cases manifesting only these initial signs are categorized as mildly toxic.⁵⁸

Symptoms of severe acute nickel carbonyl poisoning generally develop over the course of several hours to days and may be associated with acute respiratory distress syndrome (ARDS) and interstitial pneumonitis. Myocarditis, marked by prolonged changes on electrocardiography, including ST- and T-wave changes, as well as QT prolongation, has been reported.⁵⁸ Neurologic symptoms associated with severe poisoning include altered mental status, seizures, and extreme weakness that sometimes necessitate mechanical ventilation. A moderate leukocytosis (10,000–15,000 white blood cells/mm³), nonspecific opacities on chest radiography, and elevation of aminotransferases may also occur, but these tend to resolve over the course of several weeks. Deaths from nickel carbonyl are typically caused by interstitial pneumonitis and cerebral edema occurring within 2 weeks of initial exposure.⁶⁹ Autopsy studies of those dying after nickel carbonyl exposure have shown diffuse pulmonary consolidation, organizing fibrosis, cerebral edema or hemorrhage, and cardiac dilation.⁵⁶ Survivors usually recover completely, although the development of a prolonged neurasthenic syndrome can occur and may last months in some cases.⁵⁸ Clinical features of nickel carbonyl poisoning are found in [Table 99–2](#).

Noncarbonyl Nickel

There are few human cases of inhalational nickel poisoning. However, from the available data, the primary concerns

appear to be pulmonary, neurologic and, perhaps, renal.

A case report described seizure activity in two patients following occupational inhalational exposure to non-carbonyl nickel. Both patients exhibited elevated urinary nickel concentrations, with no recurrence of seizure activity upon removal from exposure.²⁰ This complication was documented previously in rats with nickel sulfate toxicity.¹⁶ Although the mechanism for this is not quite clear, animal studies indicate that inhibition of the glutamate transporter may be involved.⁴⁰ Interstitial pneumonia is also associated with inhalational exposure while spray painting high-temperature nickel-chromium alloys.²⁷ As previously mentioned, inhalational exposure to metallic nickel particles/nanoparticles can induce ARDS, as well as acute tubular necrosis.^{48,50}

Parenteral Administration. Acute parenteral toxicity from nickel-containing compounds occurred following the use of water for hemodialysis that had been heated in a nickel-plated tank.⁷⁹ The concentration of nickel in the delivered water was 0.25 mg/L, and serum concentrations exceeded 3 mg/L. Through back extrapolation, serum concentrations were estimated to have been as high as 9 mg/L. These patients developed nonspecific symptoms, including headache, nausea, and vomiting, similar to nickel carbonyl poisoning, although no respiratory complaints were reported. The effects resolved after several hours, and the patients recovered without sequelae.

Ingestion. Acute ingestions of contaminated water containing 1.63 g Ni²⁺/L caused nausea, vomiting, diarrhea, weakness, and headache, as well as pulmonary symptoms, including cough and dyspnea, lasting up to 48 hours.⁶⁷ Estimated ingested doses of nickel (as Ni²⁺) were 0.5 to 2.5 g and serum concentrations as high as 13.4 µg/L were reported. The death of a 2 year-old girl followed ingestion of 2.2 to 3.3 g Ni²⁺ in the form of nickel sulfate crystals. Following ingestion, this child reportedly developed depressed level of consciousness, nuchal rigidity, mydriasis, erythema, tachycardia, and ARDS.¹⁸

Dermal Absorption. Although transdermal absorption is typically of minor clinical significance, disruption of the normal integument may allow for more efficient systemic absorption. A metal refinery worker suffered a 40% body surface area partial-thickness chemical injury resulting from exposure to a chemical mixture that included nickel carbonate and nickel sulfate.⁴⁵ Prior to the incident, this individual's measured serum nickel concentration was 0.023 µmol/L (1.33 µg/L). On the sixth day following the injury the serum concentration was 0.490 µmol/L (28 µg/L). Two five-day courses of chelation with CaNa₂EDTA were begun for concomitant cobalt poisoning, and the patient's serum and urine nickel concentrations were within normal limits by 21 days postexposure. He subsequently recovered without manifesting signs of nickel toxicity.

Chronic Nickel Exposure

Chronic inhalational exposure to nickel is associated with injury characterized by specific histologic changes in the nasopharynx and upper respiratory tract, including atrophy of the olfactory epithelium, rhinitis, sinusitis, nasal polyps, and septal damage.¹¹ Pulmonary effects may include asthma⁴¹ and pulmonary fibrosis.^{8,24}

The International Agency for Research on Cancer classifies nickel compounds as a group 1 carcinogen (carcinogenic to humans).²⁹ The potential for and mechanisms of carcinogenesis of nickel depend heavily on the specific compounds studied. Although nickel-induced carcinogenesis is fairly well established for nickel compounds, the role of metallic nickel is less clear.⁵⁹

An increased incidence of oral cancer has been associated with geographic areas containing higher concentrations of nickel in farming soil.⁶⁴ Although earlier studies of occupationally exposed workers, primarily electroplaters and refinery workers, also showed increased rates of nasal and pulmonary tumors, more recent studies of nickel-exposed workers in more modern environments with lower permissible limits of nickel exposure do not show a significantly increased risk of cancer or any cause of mortality.^{60,61}

Although the exact mechanism of any possible carcinogenesis remains to be firmly elucidated, studies indicate several potential mechanisms. Animal studies show a threshold dose–response curve for inflammation with soluble compounds (nickel sulfate), and similar curves describe the risks of pulmonary cancers with the less-soluble nickel oxides and nickel subsulfide.⁵⁷ Reactive oxygen species (ROS) formation occurs secondary to depletion of both glutathione and protein-bound sulfhydryl groups by nickel. Accumulation of ROS leads to lipid peroxidation and DNA damage.^{62,77} Formation of ROS consequently causes depletion of ascorbic acid (vitamin C) as a free radical scavenger in conjunction with vitamin E. In vitro studies of human airway epithelial cells have shown that depletion of intracellular ascorbate due to nickel causes the induction of hypoxic stress. Such nickel-induced stress leads to the activation of hypoxia-inducible factor (HIF-1) and upregulation of hypoxia-inducible genes.⁵² Hypoxia is encountered in tumors as they outgrow their blood supply, thus selecting for cells with altered energy metabolism, changes in growth regulation, resistance to apoptosis, or both. Therefore, HIF-1 activation and the upregulation of hypoxia-inducible genes mimics intracellular permanent hypoxia and may be related to nickel-induced carcinogenesis.⁵³

Soluble compounds such as nickel sulfate cause a threshold-dependent inflammatory response and may act as promoters

of malignancies without a directly genotoxic effect. Insoluble nickel oxides and nickel sulfide bind to chromatin and nucleic acids¹⁵ and also affect expression of various mRNAs.⁷⁸ Thus, under some conditions, these compounds may be carcinogenic through genetic mechanisms, epigenetic mechanisms, or both. The more potent carcinogenic effects of insoluble nickel compounds may be a consequence of their increased cellular uptake.¹⁷

Based on concerns about long-term health effects, exposure limits for various nickel compounds have been proposed (Table 99–3).

TABLE 99–3. US Nickel Exposure Limits

ACGIH TLV-TWA	Amount (mg/m ³)	Parts per million
Elemental	1.5	
Soluble inorganic	0.1	
Insoluble inorganic	0.2	
Nickel subsulfide	0.1	
Nickel carbonyl	0.35	0.05
OSHA PEL-TWA		
Noncarbonyl nickel	1	
Nickel carbonyl	0.007	0.001
NIOSH REL-TWA		
Noncarbonyl nickel	0.015	
Nickel carbonyl	0.007	0.001

DIAGNOSTIC TESTING

Although nickel is widely distributed to many body fluids and tissues, urine and blood are the most commonly analyzed samples. Urine collection should ideally use acid-washed, metal-free containers. Some authors recommend correcting urinary nickel concentration per gram of urine creatinine, but it is not clear that this offers any particular advantage in clinical decision making. The average nickel concentration in serum is 0.3 µg/L, whereas the value in urine ranges from 1 to 3 µg/L,⁷¹ although substantially higher values are reported even in non-occupationally exposed populations.^{31,43} Concentrations among workers occupationally exposed to nickel may be substantially higher and serum concentrations of more than 8 µg/L have been proposed as being indicative of excessive exposure.⁴³

Nickel concentrations rise in urine, serum, and whole blood following oral administration. In these studies, serum concentrations were slightly higher than, but correlated well with whole blood. Urine and blood concentrations primarily reflect exposure occurring within the previous 48 hours,¹⁴ which is roughly the biologic half-life calculated from various field studies.⁷⁶

Urine nickel concentrations are used more commonly than blood for monitoring of workplace exposures and for prognostic and therapeutic decision making in nickel carbonyl exposures. An 8-hour collection is typically performed, and the average urinary excretion of nickel (in these nickel workers) is 2 µg/L, with an upper limit of normal of 5 µg/L. In cases of nickel carbonyl poisoning, concentrations of less than 100 µg/L in the initial 8-hour specimen may imply mild toxicity. Concentrations of 100 to 500 µg/L are classified as moderate, while concentrations higher than 500 µg/L are categorized as severe poisonings.⁶⁹ These classifications have been used in guiding treatment decisions. Urine nickel concentrations rise prior to the onset of symptoms in nickel carbonyl poisoning, making this determination a potentially useful screening tool for both workforce surveillance and the management of acute exposures.

Testing for allergic contact dermatitis due to nickel is performed using patch testing, as for other types of contact dermatitis. Strip patch testing is more sensitive than standard patch testing by 16%.²¹ Testing metal surfaces for free nickel is possible and sometimes necessary in the evaluation and treatment of nickel dermatitis. Patients with clinically important sensitivity or suspect medical histories can order an inexpensive, commercially packaged dimethylglyoxime spot test, allowing them to test metal objects for the presence of free nickel.¹³

TREATMENT

The first step in treatment of nickel-related medical problems is eliminating the exposure, which includes detection and removal of the source. In the case of acute exposures to nickel carbonyl, removal of clothing to prevent continued exposure and thorough skin decontamination may be necessary.

Symptomatic treatment for pulmonary symptoms associated with hypoxia includes the administration of supplemental oxygen. The use of bronchodilators and corticosteroids may also be necessary for the treatment of concomitant bronchospasm. Mechanical ventilation may be required in the most severe cases.

The administration of intravenous fluids to promote diuresis reduces the half-life of orally ingested nickel chloride by approximately 50%.⁶⁷ Due to high levels of protein binding, hemodialysis does not effectively remove nickel from the serum.⁷⁹

Chelation

Because there are no controlled human trials, specific recommendations for the use of chelation to treat nickel toxicity are not currently supported by the literature. As a result, extrapolation from animal studies and case reports form the basis for most treatment regimens. Most studies and reports involving treatment have focused on workers exposed to nickel carbonyl.

Several drugs are proposed as potential treatments for nickel carbonyl exposures. Studies in rats with various chelators show some protection by administration of British anti-Lewisite (BAL) and D-penicillamine,⁸¹ whereas calcium disodium EDTA had no protective effect.⁸⁰ Although BAL was being used in the past,⁶⁹ the most recent literature has focused on the use of diethyldithiocarbamate (DDC; Chaps. 79 and 102).

DDC is a chelator formerly used as the color reagent for urine nickel measurements. Rats exposed to several times the LD₅₀ (median lethal dose for 50% of volunteers) for nickel carbonyl had dramatically reduced mortality when pretreated with DDC; however, the antidotal efficacy decreased with increasing delay to treatment.⁶ A proposed treatment regimen for exposed workers focused on analysis both of the exposure and of the initial 8-hour urine collection.⁶⁹ Patients with suspected severe poisonings are typically given the first gram of DDC in divided oral doses. When less-severe exposures are suspected, treatment decisions are based on the urinary nickel concentration. At concentrations below 100 µg/L, no initial therapy is recommended as delayed symptoms are unlikely to develop. At concentrations between 100 and 500 µg/L, an oral regimen consisting of 1 g DDC initially, 0.8 g at 4 hours, 0.6 g at 8 hours, and 0.4 g at 16 hours is used. DDC is continued at a dose of 0.4 g every 8 hours until there is symptomatic improvement and urine nickel concentration is normal. Severe exposures with urinary nickel concentrations more than 500 µg/L can be treated using the same regimen, although these patients frequently require closer monitoring. Critically ill patients are given parenteral DDC starting at a dose of 12.5 mg/kg. However, given the animal data that the route and timing of administration are important to survival, some authors recommend that parenteral DDC be given as soon as possible following nickel carbonyl poisoning.¹² Although typically well-tolerated, DDC is capable of inducing a disulfiram reaction (Chap. 79) if taken with alcohol, and there are concerns about using DDC when there is concurrent cadmium exposure, at least by the oral route.³ As with many chelators, there is also debate about whether the redistribution of nickel by chelating agents may be detrimental by increasing brain and organ concentrations.⁴⁶

Disulfiram is metabolized into two molecules of DDC. Given that DDC is not pharmaceutically available in the United States, there is some interest in the use of disulfiram as an antidote for nickel carbonyl. Although case reports describe successful treatment of nickel carbonyl toxicity with disulfiram,³⁵ concern exists because animal studies show that disulfiram increased nickel concentration in brain tissue.⁵ Disulfiram cannot be considered a standard of care, due to lack of convincing evidence, but would be recommended due to its theoretical efficacy. One treatment regimen was 750 mg given orally every 8 hours for 24 hours, followed by 250 mg every 8 hours.³⁵

Considering most of the literature and almost all human case reports of nickel carbonyl refer to the use of DDC, it is considered the treatment of choice for nickel toxicity. Although commonly available as a reagent, pharmaceutical-grade DDC is not produced commercially. While based on less robust evidence, given the fact that disulfiram is essentially a prodrug for the unavailable DDC, treatment of nickel carbonyl poisonings with disulfiram is recommended.

Treatments evaluated for divalent nickel exposure are D-penicillamine and N-benzyl-D-glucamine dithiocarbamate, which, while not commonly available, more effectively lowers brain nickel concentrations than does DDC, perhaps because of its lower lipid solubility.⁷⁰

Contact dermatitis from nickel is treated using standard measures, including avoidance, topical steroids, and oral antihistamines. Some patients have benefited from dietary alteration to reduce nickel intake. Although sometimes advised, there does not appear to be a role for avoiding stainless steel cookware to reduce the nickel content of food.¹

SUMMARY

- Nickel is a ubiquitous metal today.
- Allergic dermatitis due to hypersensitivity is the most common type of nickel-related disease.
- Nickel toxicity is rare and most often related to nickel carbonyl.
- There is inadequate evidence to consider chelation for toxicity.

- Chronic, excessive exposures to nickel compounds may increase the risk of aerorespiratory cancers.

100 SELENIUM

Diane P. Calello

Selenium (Se)	
Atomic number	= 34
Atomic weight	= 78.96 Da
Normal concentrations	
Whole blood	= 0.1–0.34 mg/L (1.27–4.32 μ mol/L)
Serum	= 0.04–0.6 mg/L (0.51–7.6 μ mol/L)
Urine	< 0.03 mg/L (0.38 μ mol/L)
Hair	= 0.4–1.4 μ g/g (0.01 μ mol/g)

HISTORY AND EPIDEMIOLOGY

Selenium was discovered by Jöns Berzelius in 1817 as a contaminant in sulfuric acid vats that caused illness in Swedish factory workers. He originally believed it to be the element tellurium (from the Latin tellus, meaning “earth”); however, on finding it to be an entirely new, yet similar, element, he named it from the Greek selene, meaning “moon.” Selenium has unusual light-sensitive electrical conductive properties, leading to its widespread use in industry. The long-term health benefits and risks of selenium are the subject of much recent investigation. It is both an essential component of the human diet and a poison.

In the 1970s, the role of selenium as an essential cofactor of the enzyme glutathione peroxidase was discovered. Keshan disease, an endemic cardiomyopathy, was described in 1979 in Chinese women and children who chronically consumed a selenium-poor diet.¹¹ Kashin-Beck disease, a disease causing shortened stature from chondrocyte necrosis, is described in young children in Russia, China, and Korea; although other etiologies are also likely responsible, partial improvement results from selenium supplementation.^{3,18} Selenium is currently being investigated for the prevention and treatment of a myriad of conditions, including autoimmune thyroiditis, cancer, Alzheimer disease, depression, and tropical leishmaniasis.³⁸ However, it is becoming more evident that “the moon” has two faces, as reports emerge that selenium supplementation may increase the risk of diabetes, amyotrophic lateral sclerosis, and some forms of malignancy.^{20,46}

The recommended daily allowance (RDA) in the United States of selenium for adults was established in 1980 at 55 μ g/d. This was determined based on the degree of supplementation required to achieve optimal glutathione peroxidase activity in selenium-deficient study populations, and the amounts required to cause overt toxicity. Deficiency occurs when daily intake falls below 20 μ g/d.¹¹

Chronic selenium toxicity, or selenosis, was first described in animals. It manifested as the acute syndrome of “blind staggers,” and the more chronic “alkali disease” affected livestock eating plants grown in highly seleniferous soil. Findings included blindness, walking in circles, anorexia, weight loss, ataxia, and dystrophic hooves. Humans in seleniferous areas of China and Venezuela develop similar integumentary symptoms (dermatitis, hair loss, and nail changes) at an intake of approximately 6000 μ g/d.^{5,41} In recent years, there have been several outbreaks of chronic selenium toxicity related to improperly formulated dietary supplements.^{7,14,47}

Selenium is widely distributed throughout the Earth’s crust, usually substituting for sulfur in sulfide ores such as marcasite (FeS₂), arsenopyrite (FeAsS), and chalcopyrite (CuFeS₂). It is found in the soil where it has leached from bedrock, in groundwater, and in volcanic gas. The highest soil concentrations of selenium in the United States are in the Midwest and the West, specifically areas of the Dakotas, Wyoming, Nebraska, Kansas, Utah, Colorado, Arizona, and New Mexico.³ Dietary selenium is easily obtained through meats, grains, and cereals. Brazil nuts, grown in the foothills of the highly seleniferous Andes Mountains, contain the highest concentration measured in food, but chronic selenium toxicity from Brazil nuts has not been reported.^{3,22}

In industry, selenium is generated primarily as a byproduct of electrolytic copper refining and in the combustion of rubber, paper, municipal waste, and fossil fuels. Selenium compounds are used in glass manufacture and coloring, photography, xerography, rubber vulcanization, and as insecticides and fungicides. Selenium sulfide is the active ingredient

in many antidandruff shampoos. Gun bluing solution, used in the care of firearms to restore the natural color to the gun barrel, is composed of selenious acid in combination with cupric sulfate in hydrochloric acid, nitric acid, copper nitrate, or methanol. [Tables 100–1 and 100–2](#) list features and regulatory standards of common selenium compounds.

TABLE 100–1. Selenium Compounds

<i>Name</i>	<i>Chemical Formula</i>	<i>Oxidation State</i>	<i>Uses</i>
Selenium (elemental)	Se	0	Photography, catalyst, dietary supplement, xerography
Selenium sulfide	SeS ₂	2 [−]	Antidandruff shampoo, fungicide
Hydrogen selenide	H ₂ Se	2 [−]	—
Dimethylselenide	CH ₃ SeCH ₃	2 [−]	Metabolite, garlic odor
Selenium dioxide	SeO ₂	4 ⁺	Catalyst, photography, glass decolorizer, vulcanization of rubber, xerography
Selenium oxychloride	SeOCl ₂	4 ⁺	Solvent, plasticizer
Selenious acid	H ₂ SeO ₃	4 ⁺	Gun bluing solution
Sodium selenite	Na ₂ SeO ₃	4 ⁺	Glass and porcelain manufacture
Selenium hexafluoride	SeF ₆	6 ⁺	Gaseous electrical insulator
Sodium selenate	Na ₂ SeO ₄	6 ⁺	Glass manufacture, insecticide

TABLE 100–2. Selenium Regulations and Advisories

Oral—Recommended Intake and Exposure Limits			
RDA (2000)		55 µg/d ^a	(0.8 µg/kg/d)
NAS-TUL		400 µg/d	(5.7 µg/kg/d)
ATSDR-chronic oral MRL ^b		5 µg/kg/d	
Water—Limits			
WHO	Drinking water	0.01 mg/L	
FDA	Bottled water	0.05 mg/L	
EPA	MCL, drinking	0.05 mg/L	
Air—Limits^c			
NIOSH			
	REL (TWA)	0.2 mg/m ³	
	IDLH	1.0 mg/m ³	
OSHA			
	PEL (TWA)	0.2 mg/m ³	

^aValues differ for pregnant and lactating women, children, and neonates. ^bNo acute or intermediate MRL has been established. Chronic ≥ 365 days. ^cAmbient background air concentrations are usually in the ng/m³ range. AHTSDR = American Toxic Surveillance and Disease Registry; EPA = Environmental Protection Agency; FDA = Food and Drug Administration; IDLH = immediately dangerous to life or health; MCL = maximum contaminant level; MRL = minimal risk level; NAS = National Academy of Sciences; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; RDA = recommended daily allowance; REL = recommended exposure limit; TUL = tolerable upper limit; TWA = time-weighted average; WHO = World Health Organization.

CHEMICAL PRINCIPLES

Selenium is a nonmetal element of group VIA of the periodic table along with oxygen, sulfur, tellurium, and polonium. Selenium exists in elemental, organic, and inorganic forms, with four important oxidation states: selenide (Se^{2-}), elemental (Se^0), selenite (Se^{+4}), and selenate (Se^{+6}). Water solubility generally increases with oxidation state. Selenium behaves similarly to sulfur in its tendency to form compounds and in biologic systems³ and is both photovoltaic (able to convert light to electricity) and photoconductive (conducts electricity faster in bright light), which has led to its use in photography, xerography, and solar cells.

At least three solid allotropes of elemental selenium are described, including “grey selenium,” which predominates at room temperature, red crystalline selenium, and a red amorphous powder.³ In general, toxicity from elemental selenium is rare and only occurs from long-term exposure. Hydrogen selenide (H_2Se) is formed from the reaction of water or acids with metal selenides or from the reaction of hydrogen with soluble selenium compounds; at room temperature, it exists in gaseous form and results in industrial inhalation exposures. The organic alkyl selenides (dimethylselenide, trimethylselenide) are the least toxic and are byproducts of endogenous selenium detoxification (methylation). Inorganic salts and acids are responsible for all cases of acute toxicity. Selenious acid (H_2SeO_3), generated from the reaction of selenium dioxide with water, is the most toxic form of selenium; ingestion of selenious acid is often fatal.

PHARMACOLOGY AND PATHOPHYSIOLOGY

Selenium exists in one of three forms in the body. First, selenoproteins contain selenocysteine residues and play specific selenium-dependent roles primarily in oxidation–reduction reactions. Second, nonspecific plasma proteins bind and may aid in transport of selenium; they may directly bind selenium (albumin, globulins) or contain it as selenocysteine or selenomethionine in place of cysteine and methionine, respectively. Third, there are several inorganic forms of selenium in transit throughout the body, such as selenate, alkyl selenides, and elemental selenium (Se^0).

There are at least 25 selenoproteins—which include glutathione peroxidases, iodothyronine 5-deiodinases, and thioredoxin reductase—each of which contain a selenocysteine or selenomethionine residue at the active site.³⁸ The most studied of these is glutathione peroxidase I, which is responsible for detoxification of reactive oxygen species. Using reduced glutathione (GSH) as a substrate, glutathione peroxidase catalyses the reduction of hydrogen peroxide to water and oxidized glutathione (GSSG, or glutathione disulfide); the reaction occurs by concomitant oxidation of the selenocysteine unit on the enzyme.^{4,37} Other selenocysteine-containing proteins, such as thioredoxin reductase, have antioxidant properties. The selenocysteine-containing thyroid hormone deiodinases are responsible for the conversion of thyroxine (T_4) to the active triiodothyronine (T_3) form (Chap. 56).

In selenium deficiency, glutathione peroxidase activity is decreased, and GSH and glutathione S-transferases are increased.³⁷ Consequently, selenium-deficient rats are more resistant to substances detoxified by glutathione S-transferase, such as acetaminophen and aflatoxin B,⁶ and less resistant to other prooxidants, such as nitrofurantoin, diquat, and paraquat.⁶ In animal studies of metal toxicity, selenium also appears to modify the effects of silver, cadmium, arsenic, copper, zinc, mercury, and fluoride; conversely, vanadium, tellurium, and arsenic modify the effects of selenium deficiency or excess.^{16,19,33,41} Although it is proposed that this is accomplished through the formation of insoluble selenium–metal complexes, these relationships are not entirely understood.¹³

Less is known about the biochemical mechanism of selenium toxicity, and what is known is generally from in vitro data. Paradoxically, excess selenium causes oxidative stress, presumably as a result of prooxidant selenide (R-Se^-) anions. In addition, the replacement of selenium for sulfur in enzymes of cellular respiration may cause mitochondrial disruption, and the substitution of selenomethionine in place of methionine may interfere with protein synthesis. Integumentary effects are also most likely a result of selenium interpolation into disulfide bridges of structural proteins such as keratin.⁴⁵

PHARMACOKINETICS AND TOXICOKINETICS

Gastrointestinal (GI) absorption varies with the type of selenium, and human data are limited. Elemental selenium is the least bioavailable ($\leq 50\%$), followed by inorganic selenite and selenate salts (75%)²⁸; selenious acid is well absorbed from the lungs and GI tract ($\sim 85\%$ in animal studies⁹). Organic selenium compounds are the best absorbed ($\sim 90\%$) as determined by isotope tracers in human studies.^{3,24} A breastfed infant developed selenosis exclusively from maternal overexposure, suggesting transmission through breastmilk.⁴⁸

Inhalational absorption was reported in a group of workers exposed to selenium dioxide and hydrogen selenide gas,^{3,15} but quantitative inhalation studies in humans are not available. Dermal absorption is limited. Selenium disulfide shampoos are not systemically absorbed as measured by urinary selenium concentrations⁹ except in cases of repeated use on

excoriated skin.³⁶

The toxic dose of selenium varies widely between selenium compounds, as demonstrated by LD₅₀ (median lethal dose for test subjects: 50%) animal studies,⁴¹ making milligram per kilogram exposure estimates difficult to interpret. Elemental selenium has no reported adverse effects in acute overdose, although long-term overexposure is harmful. The selenium salts, particularly selenite, are more acutely toxic, as is selenium oxide (SeO₂) through its conversion to selenious acid in the presence of water. Selenious acid may be lethal in children following ingestion of as little as a tablespoon of 4% solution in children.

Metabolic conversion of all forms of selenium to the selenide anion occurs through various means (Fig. 100–1), after which the selenide ion undergoes one of three fates: (1) incorporation into selenoproteins such as glutathione peroxidase and triiodothyronine, (2) binding by nonspecific plasma proteins such as albumin or globulins, or (3) hepatic methylation into nontoxic, excretable metabolites. Trimethylselenide is the primary metabolite and is excreted by the kidneys, the major elimination pathway for selenium. Fecal elimination also occurs. Dimethylselenide production is usually minor but increases with exposure; this compound is volatilized through exhalation and sweat and is responsible for the garlic odor of patients exposed to excess selenium. The remaining selenium in the body is greater than 95% protein bound within 24 hours.^{1,41} Toxicokinetic data are limited and vary by compound.

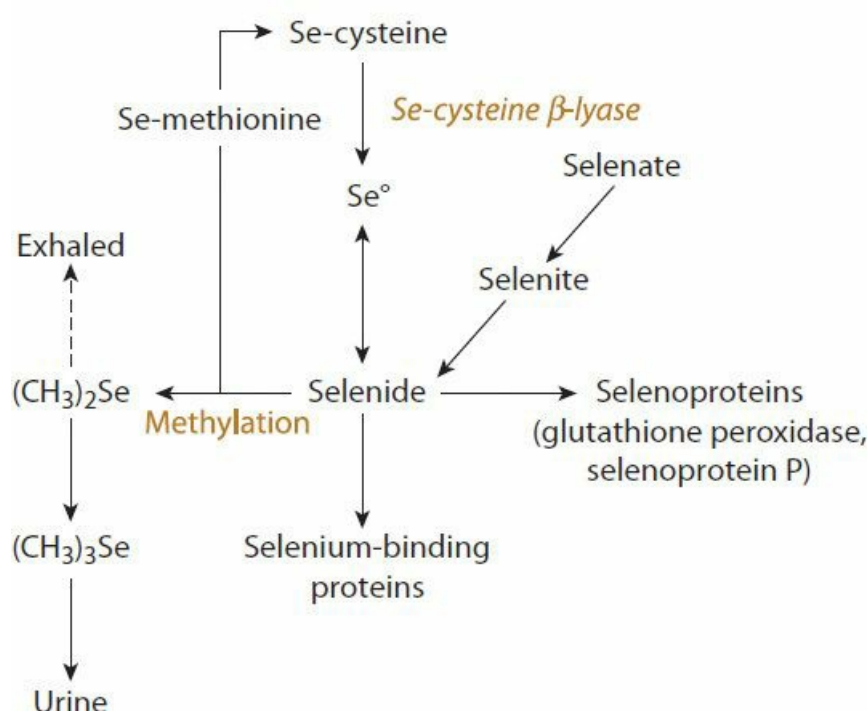

FIGURE 100–1. Metabolism of selenium. The selenide anion is central in selenium metabolism. Organic selenocysteine is converted via the β-lyase enzyme to elemental selenium and then to selenide. Selenomethionine may either undergo transsulfuration to selenocysteine or methylation to excretable metabolites. The selenate and selenite salts are reduced to selenide. Selenide then undergoes one of three processes: methylation, incorporation into selenoproteins, or binding by nonspecific plasma proteins.¹

CLINICAL MANIFESTATIONS

Acute

Dermal and Ophthalmic Exposure. Dermal exposure to selenious acid or to selenium dioxide (which is converted to selenious acid) and to selenium oxychloride (a vesicant hydrolyzed to hydrochloric acid) causes painful caustic burns.¹² Excruciating pain may result from accumulation under fingernails. Corneal injury with severe pain, lacrimation, and conjunctival edema is reported after exposure to selenium dioxide sprayed unintentionally into the face.²⁹ In chronic exposures, “rose eye,” a red discoloration of eyelids with palpebral conjunctivitis, is also described.

Inhalational Exposure. When inhaled, all selenium compounds have the potential to be respiratory irritants, although inhaled elemental selenium dusts are less injurious than those compounds that can be converted to selenious acid. Toxicity from hydrogen selenide inhalation is reported throughout the industrial literature.⁸ Hydrogen selenide is oxidized to elemental selenium, so acute toxic exposures are limited to confined spaces where the hazardous gas may accumulate; however, similar to hydrogen sulfide (H₂S), its ability to cause olfactory fatigue, rendering the exposed persons anosmic to the toxic fumes, may pose significant hazard (Chap. 26⁸ Acute exposure to high concentrations of hydrogen selenide gas

produces respiratory and mucosal irritation which may persist for years as residual restrictive and obstructive disease.³⁹

By contrast, selenium dioxide and selenium oxide fumes cause more injury through conversion to selenious acid in the presence of water in the respiratory tract. Twenty-eight workers in a selenium rectifier plant who were inadvertently exposed to smoke and high concentrations of selenium oxide in an enclosed area developed upper respiratory irritation, bronchospasm, and transient hemodynamic instability.⁴⁹ Some developed chemical pneumonitis, fever, chills, headache, vomiting, and diarrhea. Five patients required hospitalization for respiratory support, with fever, leukocytosis, and bilateral infiltrates. All patients recovered without sequelae.

Selenium hexafluoride is a caustic gas used in industrial settings as an electrical insulator. Its caustic properties are derived from its conversion to elemental selenium and hydrofluoric acid in the presence of water. Severe pain and burning of the eyes, skin, and respiratory tract similar to that seen with hydrofluoric acid exposure can occur after inhalation of selenium hexafluoride (Chap. 107).

Oral Exposure. Acute fulminant selenium toxicity occurs after ingestion of inorganic selenium compounds, the most toxic of which is selenious acid in the form of gun bluing solution. Similar toxicity may result from selenium oxide and dioxide, which are converted to selenious acid as well as sodium selenite and selenate. The underlying mechanism for this often fatal syndrome is not well understood but may stem from a multifocal disruption of cellular oxidative processes and antioxidant defense mechanisms. Elemental selenium and organic selenium compounds do not cause acute toxicity.

Some authors have proposed a “triphasic” course of acute inorganic selenium toxicity, with GI, myopathic, and circulatory symptoms as the toxic effects progress.⁴⁴ In reality, acute inorganic selenium poisoning is often rapid and fulminant, with onset of symptoms within minutes and, in some cases, death within one hour of ingestion. GI symptoms are the most commonly described and the first to occur and include abdominal pain, diarrhea, nausea, and vomiting. This may be partly caused by caustic esophageal and gastric burns but does not occur in all cases. Patients may have a garlic odor. The myopathic phase is characterized by weakness, hyporeflexia, myoclonus, fasciculations, and elevated creatine phosphokinase concentrations with normal myocardial band (MB) fraction. Acute kidney injury is also reported and presumably results from myoglobinuria and hemolysis. More severely poisoned patients may exhibit lethargy, delirium, and coma.

Circulatory failure is the hallmark of serious inorganic selenium toxicity. Patients present with dyspnea, chest pain, tachycardia, and hypotension. Initial electrocardiography (ECG) may demonstrate ST elevation, a prolonged QT interval, and T-wave inversions. Refractory hypotension occurs as a combined product of decreased contractility from toxic cardiomyopathy and decreased peripheral vascular resistance. Pulmonary edema, ventricular dysrhythmias, myocardial and mesenteric infarction, and metabolic acidosis all contribute to poor outcome in these patients.^{30,34,49} Death results from circulatory collapse in the setting of pump failure, hypotension, and ventricular dysrhythmias, often within 4 hours of ingestion.^{17,21,35,43} Other less frequent abnormalities include hypokalemia, hyperkalemia, coagulopathy, leukocytosis, hemolysis, thrombocytopenia, and metabolic acidosis with elevated lactate.^{40,44}

Chronic

Chronic elemental selenium toxicity, or selenosis, has received recent attention because of reports of improperly formulated selenium-containing dietary supplements. In 2008, at least 200 people developed painful skin lesions, diarrhea, alopecia, fever, fatigue, memory loss, and nail deformities after use of the errant supplement.^{2,27,47} The manufacturer voluntarily recalled the product, and a US Food and Drug Administration investigation revealed that the liquid supplement contained approximately 200 times the concentration stated on the packaging.¹⁰ The patients consumed approximately 40,000 µg/d while taking the supplement, or 1000 times the US RDA.² A similar outbreak occurred from a super-potent supplement in 1983, affecting at least 13 patients, all of whom recovered after discontinuation of the supplement.^{7,14}

Selenosis is similar to arsenic toxicity, with the most consistent manifestations being nail and hair abnormalities. As with arsenic toxicity, nail or hair findings alone are unlikely to be the sole evidence of selenosis, but their absence makes the diagnosis unlikely. The hair becomes very brittle, breaking off easily at the scalp, with regrowth of discolored hair and the development of an exfoliative pruritic scalp eruption with acneiform papules.²⁶ The nails also break easily, with white or red ridges that can be either transverse or longitudinal; the thumb is usually involved first, and paronychia and nail loss may develop.^{26,32} The skin becomes erythematous, swollen, and blistered, as well as slow to heal and has a persistent red discoloration. Increased dental caries may occur.²⁶ Neurologic manifestations include hyperreflexia, peripheral paresthesia, anesthesia, and hemiplegia. Although cardiotoxicity is described with both selenium deficiency and acute poisoning, no such cases are reported with human selenosis. Aside from one case described in endemically exposed patients in China⁵⁰ in which there were insufficient postmortem data, there have been no reported deaths from intermediate or chronic exposure.

Selenosis is implicated in a number of long-term environmental exposures. Many descriptions come from inhabitants of the Hubei province of China from 1961 to 1964, the majority of whom developed clinical signs after an estimated average consumption of 5000 µg/d of selenium (but as little as 910 µg/d) derived from local crops and vegetation.⁵⁰ Inhabitants of a

seleniferous area of Venezuela, consuming approximately 300 to 400 µg/d of selenium, also develop symptoms of selenium excess; however, the low socioeconomic and poor dietary status of the subjects may also contribute to their symptoms. By contrast, US residents in a seleniferous area with a high selenium intake (724 µg/d) over 2 years who were compared with a control population and monitored for symptoms and laboratory abnormalities remained asymptomatic, with only a clinically insignificant elevation of hepatic aminotransferases in the high-selenium group.^{22,25} Average selenium concentrations were serum, 0.215 mg/L; whole blood, 0.322 mg/L; and urine, 0.17 mg/L. A similar cohort with comparable blood concentrations was also reported in the Brazilian Amazon.²²

Selenosis is also reported in the industrial setting. Copper refinery workers develop garlic odor and GI and respiratory symptoms coincident with exposure to selenium dust and fumes.¹⁵ Long before workplace biologic monitoring took place, intense garlic odor of the breath and secretions was recognized as a reason to remove a worker from selenium exposure until the odor subsided. Neuropsychiatric findings such as fatigue, irritability, and depression are reported throughout the industrial literature and are difficult to quantify. Early reports describe the selenium factory worker who “could not stand his children about him” at the end of the day.¹²

Although carcinogenicity is suggested by a number of animal studies, in humans, the data available suggest, if anything, an inverse correlation between selenium intake and cancer risk. The International Agency for Research on Cancer does not list selenium as a known or suspected carcinogen.³ Animal studies also suggest that selenium has embryotoxic and teratogenic properties.¹³ A recent large randomized controlled trial of selenium supplementation reported an increased risk of diabetes mellitus with the ingestion of 200 µg/d of elemental selenium-fed baker’s yeast compared with placebo.^{20,46}

DIAGNOSTIC TESTING

Over time, selenium is incorporated into blood and erythrocyte proteins, making serum the best measure of acute toxicity and whole blood preferable for the assessment of patients with chronic exposure. Patients with acute poisoning generally have an initial serum concentration greater than 2 mg/L, which falls below 1 mg/L within 24 hours, reflecting redistribution.³² Patients with long-term elemental exposures are reported to have serum concentrations of 0.5 to 1.0 mg/L. However, there is no predictable relationship between selenium concentrations and exposure, toxicity, or time course. Population-based studies suggest an average serum concentration of 0.126 mg/L in the United States.³¹

Urine concentrations reflect very recent exposure because urinary excretion of selenium is maximal within the first 4 hours. In addition, urine concentrations are an imperfect measure because they can be affected by the most recent meal and hydration status. However, in general, a normal urinary concentration is less than 0.03 mg/L. Freezing of urine specimens after collection is recommended to retard the enzymatic formation of difficult-to-detect volatile metabolites.³²

Hair concentrations of selenium were measured in the Hubei Chinese populations of interest and during the contaminated supplement outbreak in 2008 and may be a useful qualitative measure of chronic exposure.^{26,42,50} However, the usefulness of hair selenium is limited in countries such as the United States where the use of selenium sulfide shampoos is widespread.

Other ancillary tests to assess selenium toxicity include ECG, thyroid function, platelet counts, hepatic aminotransferases, creatinine, and serum creatine phosphokinase concentrations. These are abnormal in some patients (eg, patients with selenious acid poisoning) and are not indicated in patients not expected to develop systemic toxicity.

MANAGEMENT

Pain

Aside from standard pain management strategies, a number of topical remedies for selenium burns have been suggested historically with little evidence supporting their use. For example, a 10% sodium thiosulfate solution or ointment to reduce selenium dioxide to elemental selenium is mentioned as a potential therapy for painful skin, nail bed, or ocular burns.¹² In one series, workers exposed to selenium dioxide fumes reported similar relief from inhalation of vapor from ammonium hydroxide-soaked sponges; the mechanism of this is unclear, and further study is required before this practice can be recommended.⁴⁹

Workers exposed to selenium hexafluoride gas may be treated with calcium gluconate gel to the affected areas. This is the same treatment as in hydrofluoric acid exposures, which is discussed in [Chap. 107](#).

Decontamination

As with any toxic exposure, prompt removal from the source is required if possible. Patients with dermal exposure should have their skin irrigated immediately. There are limited data to support the use of aggressive GI decontamination after the ingestion of most elemental selenium-containing xenobiotics because little expected acute toxicity is present. However, in

xenobiotics with the potential for producing systemic toxicity, such as the selenite salts, decontamination with gastric lavage or activated charcoal may be warranted. Although no activated charcoal adsorption data are available to guide this therapy, it should be considered in light of potential benefit until further information is available.

Special mention should be made of the ingestion of selenious acid. Given its toxicity, the judicious use of small nasogastric lavage may be indicated based on the time since ingestion, the amount and concentration ingested, the presence or absence of spontaneous emesis, the likelihood of caustic esophageal injury, and the clinical condition of the patient.

Chelation and Antidotal Therapy

There are no proven antidotes for selenium toxicity. Animal studies and scant human data suggest that chelation with dimercaprol (BAL),²⁴ edetate calcium disodium (CaNa₂EDTA), or succimer is not advised due to the formation of nephrotoxic complexes with selenium, do not speed clinical recovery and may, in fact, worsen toxicity.^{23,24} Arsenical compounds appear to ameliorate selenium toxicity through enhanced biliary excretion,^{8,13,15,23} but there are no studies to guide this inherently toxic therapy. Vitamin C is hypothesized to limit oxidative damage but has not been studied. Bromobenzene may accelerate urinary excretion of selenium,⁸ but its inherent toxicity limits its use, regardless of efficacy.

Extracorporeal removal techniques such as hemodialysis or hemofiltration decrease selenium concentrations in patients undergoing the procedure regularly for chronic kidney disease, so theoretically, this could be of use in lowering toxic serum selenium concentrations. However, because of extensive protein binding, this benefit may be only minor and only relevant to patients undergoing frequent dialysis. Although there are reports of using hemodialysis in patients with acute selenium poisoning, further study must occur before this can be recommended.^{19,21}

Supportive Care

This is the mainstay of therapy in selenium poisoning. In particular, patients with selenious acid toxicity require intensive monitoring and multisystem support to survive.

SUMMARY

- Selenium is an essential trace element and is required in the diet of both animals and humans.
- Ingestion of selenious acid is often fatal.
- Other selenium compounds cause variable toxicity, usually following setting of occupational exposure. Topical and inhalational exposure causes burns and pulmonary irritation, respectively. Acute systemic exposure results in gastrointestinal, myopathic, and circulatory signs and symptoms.
- Long-term exposure to elemental selenium may cause selenosis, of which alopecia is the most consistent finding.
- Although it is possible to obtain blood, urine, and hair selenium concentrations to confirm exposure, no clear relationship exists between concentration and clinical outcome.
- Supportive therapy remains the standard of care.

101 SILVER

Melisa W. Lai Becker and Michele M. Burns

Silver (Ag)		
Atomic number	=	47
Atomic weight	=	107.9 Da
Normal concentrations		
Serum	<	1 µg/L
Urine (24 hour)	<	2 µg/L

HISTORY

Although the symbol of silver, Ag, is derived from the Latin and Greek words for silver—argentum and argyros—the word used in English is derived from Slavic and Germanic Silubr and Sirebro, as well as Old English Seolfor. The alchemy symbol of silver (a crescent moon) and dalton symbol (a coinlike circumscribed letter S) convey the impression of silver as a valued and precious element.

In Asia Minor and on islands in the Aegean Sea, dumps of slag (scum formed by molten metal surface oxidation) demonstrate that silver was likely separated from lead as early as 4000 b.c. The use of silver as a precious metal with trade value appears to have begun around 600 b.c, when weighed pieces of silver were exchanged for goods. Silver coinage debuted circa 550 b.c in the Mediterranean, and was adopted by various empires, dynasties, and nation-states thereafter. Today, only Mexico uses silver in circulating coinage.

The Phoenicians and early Greeks knew to store water, wine, and vinegar in silver-lined vessels during long sea voyages, just as later American pioneers added silver coins to water barrels and jugs of milk to keep them fresh.⁴¹ The phrase “born with a silver spoon in his mouth” referred originally to health and not wealth, as silver pacifiers and baby spoons were used to help ward off childhood illnesses.

A traded commodity on the world’s markets, silver had been used as an abstract financial standard for various economies throughout modern banking history until the late 19th century. While the United States incorporates silver purely in commemorative and proof coins, the state of Utah passed the “Legal Tender Act of 2011” to allow its residents to use silver and gold coins produced by the US Mint as cash with value based on weight rather than minted face value.^{50,60}

Beyond the economic role of silver, the electrical and thermal conductive properties of the element make it an invaluable material for scientific instrument manufacture and engineering. Because silver contacts neither corrode nor overheat, silver is commonly used in electronic devices and appliances. Silver was a key component of early telecommunications—it was the choice for Morse’s first telegraph contacts in 1844—and made the jet age possible, as only silver-plated bearings have the adequate dry lubricity necessary for safe engine shutdown without volatile oil lubricants. Today, washing machines, cars, smartphones, and many types of consumer electronics, from televisions to toaster ovens, all use small amounts of silver in their functional parts.

Silver is also used to “make rain”: silver iodide crystals, whose lattice structure is similar to ice, are released into “supercooled” (between 7 and 25°F) clouds, causing water droplets in clouds to attach and form ice crystals that become large and heavy enough to drop from the cloud and melt into raindrops en route to Earth.

The medicinal value of silver has been greatly exaggerated, with the element being touted by some as a “cure-all.” In the late 19th and early 20th century, claims were made that oral administration of colloidal silver proteins (CSPs; gelatinous suspensions of finely divided elemental silver) would successfully treat diverse diseases, most without evidence.^{16,57} However, in 1960, the US Dispensary declared that “there is no justification for this internal use, either theoretically or practically,” and silver was banned in all nonprescription drugs.¹⁴ In 1999, the US Food and Drug Administration issued a Final Rule declaring that all nonprescription drug products containing colloidal silver or silver salts were “not recognized as safe and effective and are misbranded.”¹⁵ However, CSPs and other silver-containing “natural” products were reintroduced for use as health and dietary supplements and, as such, are not subject to FDA regulation under the Dietary Supplement Health and Education Act of 1994 so long as they make no claim to treat or

prevent any disease.¹⁶ After the anthrax terrorist acts of 2001, the mayor of Tampa, Florida, called for CSPs to be mixed into the town’s water supply as a protective “elixir” without scientific justification.² As silver-containing products continue to be marketed and sold online as “natural” health supplements with few warnings as to the possible development of argyria—a permanent bluish-gray discoloration of the skin from chronic silver overexposure—there has been a small resurgence of case reports of argyria since the turn of the 21st century.¹⁹

EPIDEMIOLOGY

Humans are exposed to minute amounts of silver upon occupation: Silver is released into the environment during silver nitrate manufacture for use in photography (diminishing), mirrors, plating, inks and dyes, and porcelain; as well as for germicides, antiseptics, caustics, and analytic reagents. Silver-salt catalysts, used for oxidation-reduction and polymerization reactions, are another source of silver exposure, as are silver powder pigments and paints.³¹ Workplace exposure is often via transdermal, transmucosal, or inhalational routes as silver particles are liberated during various mining, refining, and manufacturing processes.

Additionally, industrial exposure of workers involved in silver mining and manufacturing increases the workplace risk of generalized argyria, although development of signs of argyria from uninterrupted occupational exposure reportedly takes up to 24 years.¹¹ Employees are susceptible to localized argyria following repeated topical exposure and corneal argyrosis (permanent ashen-grey discoloration of the conjunctiva) from working with smaller amounts of silver in specific applications, as in the coating of metallic films on glass and china, manufacture of electroplating solutions and photographic processing, preparation of artificial pearls, and simple cutting and polishing of silver.

Both the National Institute for Occupational Safety and Health and the Occupational and Safety Health Administration of the United States have established the safe occupational exposure limit to silver metal and soluble compounds as 10 µg/m³ air per 8-hour work shift. The estimated oral intake of silver from average environmental exposure for humans not working in silver-related industries ranges from 10 to 88 µg/d.¹³

Pharmacology

Following absorption, silver is transported by globulins in blood and stored mainly in skin and liver, with average daily intake excreted in the bile and eliminated in the feces (up to 30–80 µg/d) and urine (up to 10 µg/d).¹⁴ Silver elimination through the feces occurs in two phases: phase one has a relatively short $t_{1/2}$ ranging from 1 to 2.4 days, varying with route of administration (apparent $t_{1/2}$ is: oral, 1 day; inhalational, 1.7 days; intravenous, 2.4 days),^{14,17,39} and phase two elimination has a $t_{1/2}$ of 48 to 52 days, thought to represent liver deposition and clearance.^{34,40}

Although study of a single human showed 18% of an orally administered silver acetate salt was retained after 30 weeks, animal studies show little silver absorption along the GI tract, with 90% of ingested silver excreted within 2 days of ingestion.¹³

Humans retain up to 10% of their daily silver exposure of 10 to 88 µg/d.⁵⁹ Minute amounts of silver can accumulate in humans throughout life, with a possible estimated lifetime accumulation of 230 to 480 mg by 50 years of age.¹³

Silver has a 1⁺(Ag⁺) valence when bonding with other elements and compounds to form complex ions and salts. Because of the microcidal effects of silver cations at low concentrations,⁴⁹ silver is used for potential medicinal and bactericidal effects.

The antibacterial activity of silver is related to both direct binding to biotic molecules and to disruption of hydrogen ions and thus, pH balance. Silver ions bind to electron donor groups of proteins (sulfhydryl, amine, carboxyl, phosphate, and imidazole) to inhibit enzymatic activities and provoke protein denaturation and precipitation.¹⁶ Silver also intercalates with DNA without destroying the double helix, thereby inhibiting fungal DNase.¹⁴ Silver ions induce proton leakage through a bacterial (*Vibrio cholerae*) membrane, leading to loss of the proton motive force in oxidative phosphorylation, with subsequent energy loss and cell death.¹⁰ Bacterial resistance to silver was not reported until the mid 1970s, followed shortly thereafter by the identification of the genes for silver resistance in bacteria.⁴⁹

Although banned from routine administration via intravenous, intramuscular, and oral routes in the United States, silver salts are approved for use in topical medications, either as a caustic styptic (hemostatic) or as a key component of burn care. Approved medicinal uses for silver in the United States apply only to silver salts and compounds and specifically preclude use of elemental silver (Table 101–1).

TABLE 101–1. Medicinal Silver Containing Products

<i>Product Name/Device</i>	<i>Route of Administration/ Exposure</i>	<i>Applications</i>
Silver nitrate (1% AgNO ₃)	Ophthalmic	Prevention of gonorrheal ophthalmia neonatorum
Silver nitrate (10% AgNO ₃)	Cutaneous	Chemical cautery of mucosa and exuberant granulations (eg, in podiatry for corns, calluses, impetigo vulgaris, plantar warts, and papillomatous growths)
Silver sulfadiazine (0.2% or 1% micronized silver sulfadiazine)	Cutaneous	Antimicrobial adjunct for prevention and treatment of wound infection for patients with second- and third-degree burns
Silver-impregnated catheters and tubes	Nanoparticle coating	Antimicrobial adjunct for use in catheters (foley catheters, central venous catheters, extra ventricular drains, and endotracheal tubes)
Silver acetate	Mucocutaneous	Used in gum, sprays and lozenges as smoking cessation adjunct. Silver combined with smoke creates an unpleasant metallic taste in the user's mouth. ²⁸

Today silver is used in water filtration cartridges and supermarket products for washing vegetables; it was used to sterilize recycled drinking water on the Russian MIR space station and NASA space shuttle.⁴⁹ Silver sulfadiazine added to burn dressings kills bacteria and increases the rate of reepithelialization across partial-thickness wounds.⁹ However, concerns associated with long-term toxicity may limit use.^{8,55}

Central venous catheters impregnated with silver sulfadiazine and silver-impregnated Foley catheters have been used to lower rates of infection.³⁵ For example, extraventricular drains impregnated with silver have had one-half of the CSF infection risk as plain catheters.²⁷ In addition, silver-lined endotracheal tubes have been shown to reduce the risk of ventilator-assisted pneumonia by up to 51%, including specifically drug-resistant pathogens such as methicillin-resistant *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Acinetobacter baumannii*.⁴⁸

PATHOPHYSIOLOGY

In great enough quantities, silver manifests cardiovascular, hepatic, and hematopoietic toxicity. Acutely, administration of 50 mg or more of particulate metallic (colloidal) silver intravenously in humans is fatal, leading to pulmonary edema, hemorrhage, and necrosis of bone marrow, liver, and kidneys.¹⁴ The mechanism for this acute toxicity was studied only in the water flea (*Daphnia magna*) where silver blocks Na⁺, K⁺-adenosine triphosphate activity.⁴ Toxicity in animals is listed by system (Table 101–2).

TABLE 101–2. Silver Toxicity: Systemic Manifestations

Cardiovascular	Rats given 0.1% silver nitrate in drinking water for 218 days developed ventricular hypertrophy that was not attributable to silver deposition in the heart despite advanced pigmentation in other body organs. ³⁸
Hepatic	Vitamin E and selenium-deficient rats developed hepatic necrosis with ultrastructural changes after administration of silver salts. ^{7,10,54} Silver can induce selenium deficiency that consequently inhibits synthesis of the selenoenzyme glutathione peroxidase.
Hematologic	Topical application of silver correlated with bone marrow depression with subsequent leukopenia or aplastic anemia. ⁷
Renal	Tubular lesions are demonstrated in animals, and acute tubular necrosis is rarely identified in humans. ³²
Neurologic	Silver deposits in peripheral nerves, basal membranes, macrophages, and elastic fibers were found in one reported case of a 55 year-old woman with progressive vertigo, cutaneous hypoesthesia, and weakness after self-administration of silver salts to treat oral mycosis for 9 years. ⁵⁶ Seizures were reported in a schizophrenic patient who ingested > 20 mg silver daily for 40 years. Serum silver concentrations were elevated (12 µg/L). Seizures resolved concurrently with discontinuation of silver ingestion and a subsequent decrease in silver serum concentration (12 µg/L). Seizures resolved concurrently with discontinuation of silver ingestion and a subsequent decrease in silver serum concentration. ³⁷
Dermatologic	Generalized argyria, localized argyria, and argyrosis (silver deposition in the eyes) developed after chronic administration of silver.

Silver is not classified as to human carcinogenicity and has not been found to be mutagenic; and no data link therapeutic use of silver to human cancer.¹³ Although studies in animals show that silver implanted subcutaneously can lead to local sarcoma formation, the EPA has deemed this reaction questionable with regard to human carcinogenicity, as implantation of other insoluble solids, such as plastic and smooth ivory, in animals produce similar results.¹³ Colloidal silver injected into rats induces growths at injection sites, but intramuscular injections of silver powder have not induced cancer.¹⁸ Local inflammatory responses notwithstanding, silver is considered an inert substance and not a human carcinogen.

Argyria

The most significant effect of silver overexposure in humans is argyria, a permanent bluish-gray discoloration of skin resulting from silver throughout the integument (Figs. 101–1 and 101–2).

FIGURE 101-1. Argyria, the slate or silver discoloration of the skin that results from silver overexposure is demonstrated in this image of herself. (Used with permission of Rosemary Jacobs.)

FIGURE 101-2. Long-term exposure to AgNO_3 in the workplace led to this patient's characteristic pigment changes of argyria. A normally pigmented arm is across the patient's chest. (Used with permission of New York University Department of Dermatology.)

Generalized argyria develops in stages, beginning with an initial gray-brown staining of gingiva, progressing to hyperpigmentation and bluish-gray discoloration in sun-exposed areas. Later, nail beds, sclerae, and mucous membranes become hyperpigmented; on autopsy, viscera are noted to be blue.

Cases of argyria have been reported in the medical literature since at least the early 19th century. One of the most famous cases of argyria is that of the Barnum and Bailey Circus' "Blue Man" who died at New York's Bellevue hospital in 1923 and was described on autopsy as follows²¹: "The color of the skin was of an unusually deep blue and from a distance appeared almost black. This deep color was almost uniform throughout the entire body, although it was more intense over the exposed skin areas." An American woman who developed argyria as a teenager during the 1950s from use of a nasal CSP for allergies has described her story on the Internet to warn others of the effects of prolonged contact with, or ingestion of, silver salts.²⁴ Her appearance was documented as an Image in Clinical Medicine in the New England Journal of Medicine.⁶ In 2002, libertarian party Montana legislator Stan Jones became known as the "blue" lawmaker who promoted the use of colloidal silver health supplements and developed argyria after manufacturing his own colloidal silver at home out of fears that the Y2K (year 2000) problem might cause a shortage of antibiotics.^{3,43}

Generalized argyria can result from either simple mechanical impregnation of skin by silver particles or inhalational and oral absorption of particulate silver. Local routes of silver absorption may be through the conjunctiva or oral mucous membranes after long-term topical treatment with silver salts.

Argyria occurs at exposure doses much lower than those associated with acutely toxic effects of silver; the degree of discoloration is directly proportional to the amount of silver absorbed or ingested.²⁰ The threshold dose for silver accumulation and retention resulting in generalized argyria varies considerably. Discoloration is reported from as little as a cumulative 1 g of metallic silver administered intravenously (from 4 g of silver arsphenamine used to treat syphilis over a 2-year period in the early 1900s), whereas others tolerated infusions containing up to 5 g of elemental silver over 9 months before clinical change was noted.²⁰

In 2002, a 42 year-old European man developed argyria after just 4 years of weekly application of a topical nasal vasoconstrictor (Coldargan, Siegfried, Sweden) available in Austria. The patient used this product to treat his rhinitis medicamentosa (rebound nasal congestion brought on by extended use of topical decongestants); each drop of medication contained 0.85 mg silver protein, which was considerably more than expected in chronic occupational exposure.⁵² More directly, colloidal silver protein ingestion for "health supplementation" leads to body burdens of silver that can produce argyria. In 1933, argyria was reported in a 33 year-old woman who had ingested 48 mg/d of elemental silver (from silver nitrate capsules) during alternating 2-week periods over 1 year to treat chronic gastrointestinal symptoms.⁵ Her serum silver concentrations remained at 500 µg/L for 3 months after discontinuation of the capsules, indicating significant silver deposition in tissues.

Mechanical impregnation of silver produces localized argyria following repeated contact with metallic silver or silver salts.²⁶ Localized argyria is reported from both implanted acupuncture needles and short-contact acupuncture, when particle deposition may occur from silver needles used repeatedly during brief therapeutic sessions.²⁹ Silver sulfadiazine use produces localized argyria in and around wound scars.^{17,55} Localized argyria of the tongue and gingiva is described in patients with silver dental amalgams.^{25,44} These patients may also have elevated tissue concentrations of silver, but there are no known cases of significant absorption resulting in generalized argyria.¹² Even the longstanding wearing of silver earrings has resulted in local contact argyria.^{33,51,53} Corneal argyrosis was frequently reported from prolonged use of colloidal silver disinfectant eyedrops; however, because these drops are no longer used, the condition has become an occupational disease caused by both inadequate eye protection and workers rubbing eyes with hands contaminated by silver particles.^{45,47,61}

Histopathology of Argyria

There are no pathologic changes or inflammatory reactions visible at a histologic level from silver deposition or impregnation. Rather, the skin discoloration of argyria comes from the silver itself and from the induction of increased melanin production. Silver granules are initially found within fibroblasts and macrophages, then extracellularly along the basement membrane of blood vessels, sweat glands, dermoepidermal junction, and beside erector pili muscles (Chap. 18). Patients with argyria commonly manifest increased pigmentation over sun-exposed skin. While the mechanism for this process is not yet fully understood, it has been proposed that silver-complexed proteins are reduced to their elemental form via photoactivation from sunlight, similar to photographic image development. Silver plus light then further stimulate melanogenesis, increasing melanin in light-exposed areas and enhancing this cycle.

Recent evidence demonstrates how silver comes to deposit in the skin: ingested silver nanoparticles dissolve in the acidic environment of the stomach, forming silver ions that are transported by glutathione and other biomolecules after absorption. These ions are reduced in the skin by sunlight and sulfur. Subsequently selenium ions align or collocate alongside silver atoms creating blue discoloration.³⁰

Skin biopsy can confirm the diagnosis of argyria, showing brown-black clusters of silver granules.

Diagnostic Testing

Urine and serum concentrations of silver can be measured as indices of silver exposure. Hair is also tested for silver, but airborne silver particles may bind to hair and contaminate samples.

In individuals without a history of medicinal silver ingestion or occupational exposure, the normal serum silver concentration is no more than 0.005 µg/mL, normal urinary silver concentration is no more than 0.005 µg/g, and normal fecal silver concentration is 1.5 µg/g.¹¹ In contrast, workers who smelt and refine silver or who prepare silver salts for use in the photographic industry, have had mean serum concentrations measured of 11 µg/L, urine silver concentrations of less than 0.005 µg/L, and fecal silver concentrations of 15 µg/g.¹¹

Treatment of Argyria

Chelators are ineffective in treating both silver toxicity and argyria.¹⁴ Dermatologic conventional wisdom has suggested that topical hydroquinone 5% may reduce the number of silver granules in the upper dermis and around sweat glands, as well as diminish the number of melanocytes.⁷ Sunscreens and opaque cosmetics can prevent further pigmentation darkening from sun exposure.

Successful treatment of argyria using laser technology has only recently been reported but appears promising with one case report of a full cure.^{22,42}

As oxidant deficiencies may enhance silver toxicity, antioxidants, such as selenium and vitamin E, may also play a role in reversing effects of silver exposure. Selenium-dependent glutathione peroxidase synthesis is diminished when silver binds to, and thus reduces, intracellular selenium.^{7,54} Supplemental vitamin E and selenium increase tolerance for silver in rats and chickens.⁸ Selenium and sulfur have been considered as possible treatments for argyria. Although the collocation of selenium with silver nanoparticles promotes argyria, selenium may act to precipitate or chelate silver by forming silver selenide complexes; in addition, silver selenide is insoluble in vivo and should reduce the availability of monovalent silver to interfere with normal enzymatic activities.^{1,36,46} Hence, increased selenium intake is theorized to bind silver for excretion rather than skin deposition. Silver–sulfur complexes may be investigated for similar effect, although the silver–sulfur complex is not as stable.⁴⁶

EMERGENCY MANAGEMENT

Although systemic toxicity of silver is predominantly a result of chronic exposure, clinicians may rarely encounter a patient who has ingested a colloidal silver product, a silver-containing medicinal product, or a silver salt. Emergency management should take into consideration the type of silver ingested.

Burns from silver-salt cautery should be managed as burns; ingested cautery should be treated as a caustic agent. Patients who ingest elemental silver should be managed supportively, as elemental silver should pass through the GI tract unchanged. Silver-salt ingestion (such as silver nitrate) should be treated as a caustic ingestion (**Chap. 106**). There is no support for gastric lavage or administration of activated charcoal as a decontamination method.

SUMMARY

- Silver toxicity—primarily argyria and burns—is still occasionally encountered^{23,52,57,58}; the workplace environment and health supplementation products are the main sources of exposure.
- Despite frequent therapeutic use of silver and silver compounds, there is no evidence of silver acting as a mutagen or carcinogen in humans.
- Significant toxicity is very rare, although argyria from chronic silver use is invariably a permanent manifestation.
- There are no proven effective means for removing accumulated silver and reversing argyria, although as of this publication there is one case report of “complete cure” through the use of lasers.

102 THALLIUM

Maria Mercurio-Zappala and Robert S. Hoffman

Thallium (Tl)		
Atomic number	=	81
Atomic weight	=	204.37 Da
Normal concentrations		
Whole blood	<	2 µg/L (9.78 nmol/L)
Urine (24 hour)	<	5 µg/L (24.5 nmol/L)

HISTORY AND EPIDEMIOLOGY

Thallium (Tl^0), a metal with atomic number 81, is located between mercury and lead on the periodic table. Thallium is a soft, pliable metal that melts at 572°F (300°C), boils at 2699.6°F (1482°C), and is essentially nontoxic. Thallium forms univalent thallos (Tl^{+1}) and trivalent thallic (Tl^{+3}) salts, which are highly toxic. Thallium is a commonly found constituent of granite, shale, volcanic rock, and pyrites used to make sulfuric acid and is also recovered as flue dust from iron, lead, cadmium, and copper smelters.²⁵

In the early 1900s, thallium salts were used medicinally to treat syphilis, gonorrhea, tuberculosis, and as a depilatory for ringworm of the scalp.^{8,68} Although the usual oral dose given for ringworm was 7 to 8 mg/kg, fatal doses ranged from 6 to 40 mg/kg.^{15,57} Many cases of severe thallium poisoning (thallotoxicosis) resulted from this treatment for ringworm, with one author summarizing nearly 700 cases and 46 deaths.⁷¹

Because thallium sulfate is odorless and tasteless, it was also successfully used as a rodenticide. Commercially available as Thalgrain, Echol's Roach Powder, Mo-Go, Martin's Rat Stop liquid, and Senco Corn Mix, thallium sulfate was a very efficient rodenticide. As a consequence of numerous case reports of unintentional poisonings,^{71,72,83} the use of thallium salts as a household rodenticide was restricted in the United States in 1965. Ultimately, even the commercial use of thallium salts as a rodenticide was banned in the United States in 1972 because of continued reports of human toxicity.

Life-threatening unintentional poisoning continues to occur in other countries, especially where thallium salts are still commonly used as rodenticides.^{2,14,81,89,97,106} Additional cases of thallium poisoning are reported in the United States and other countries as a result of the use of thallium for homicide^{21,62,67,75,77,86,94} and through contamination of herbal products⁹¹ and illicit drugs such as heroin^{1,80} and cocaine.⁴⁴ Although occupational exposures to consequential amounts of thallium salts are uncommon, occupational toxicity is well described.³⁸

The following discussion of thallium toxicity refers to toxicity resulting from exposure to inorganic thallium salts, which represents virtually the entire literature on thallium poisoning. Although exceedingly rare, cases of poisoning with organic thallium compounds are reported⁴ and should be assessed and managed in a fashion similar to that used for patients with inorganic exposures. Although small amounts of thallium salts are used as radioactive contrast to image tumors and to permit the visualization of cardiac function, the doses used are insignificant without potential for thallium toxicity.⁶⁸

TOXICOKINETICS

Exposures usually occur via one of three routes: inhalation of dust, ingestion, and absorption through intact skin. Thallium is rapidly absorbed following all routes of exposure. Bioavailability is greatest after ingestion and exceeds 90%.⁴⁰ Distribution follows three-compartment toxicokinetics⁸² (Chap. 9) into a final volume of distribution that is estimated to be about 3.6 L/kg.¹⁹ Thallium can be found in all organs, but it is distributed unevenly, with the highest concentrations found in the large and small intestine, liver, kidney, heart, brain, and muscles.^{8,52} In animals, the highest concentrations of thallium are found in the kidneys.^{3,52}

The toxicokinetics of thallium can be described in the following three-phase model. The first phase occurs within the first 4 hours after oral exposure during which thallium is distributed to a central compartment and to well-perfused

peripheral organs such as the kidney, liver, and muscle. In the second phase, which may last between 4 and 48 hours, thallium is distributed into the central nervous system (CNS).⁸² Whereas some literature suggests that this distribution phase is generally completed within 24 hours of ingestion,⁸² one human case suggests slower distribution into the CNS as evidenced by increasing cerebrospinal fluid (CSF) concentrations in the days after exposure when blood concentrations were declining, which thereby excludes ongoing absorption.⁹⁴ The third or elimination phase usually begins within 24 hours after ingestion. The primary mechanism of thallium elimination is secretion into the intestine, but enteral reabsorption of thallium that is present in the bile subsequently reduces the fecal elimination.^{19,67} Thallium is excreted primarily via the feces (51.4%) and the urine (26.4%).⁵⁶ It is filtered by the glomerulus, with approximately 50% being reabsorbed in the tubules. Thallium is also secreted into the tubular lumen in a manner similar to potassium.⁷ The duration of the elimination phase depends on the route of exposure, dose, and treatment. Unlike many other metals, thallium does not have a major anatomic reservoir. For this reason, reported elimination half-lives are as short as 1.7 days in humans with thallium poisoning.⁴²

PATHOPHYSIOLOGY

The mechanism of thallium toxicity is not well established. Thallium behaves biologically in a manner similar to potassium because both have similar ionic radii (1.47 Å for thallium and 1.33 Å for potassium). Because cell membranes cannot differentiate between thallous (Tl^{+1}) and potassium (K^{+}) ions, thallous ions accumulate in areas with high potassium concentrations, such as the central and peripheral nervous system and hepatic and muscle tissue.^{63,106} This accumulation is the fundamental principle that governs the use of radioactive thallium in cardiac imaging studies. Thallium replaces potassium in the activation of potassium-dependent enzymes.⁶³ In low concentrations, thallium stimulates these enzyme systems, but in high concentrations, it inhibits them.^{9,65} Pyruvate kinase, a magnesium-dependent glycolytic enzyme that requires potassium to achieve maximum activity, has 50 times greater affinity for thallous ions than potassium ions.⁴⁸ Succinate dehydrogenase, an essential enzyme in the Krebs cycle, is inhibited by small doses of thallium in rats.³⁷ Sodium-potassium adenosine triphosphatase (ATPase), which is responsible for active transport of monovalent ions across cell membranes, can use thallous ions at extremely low concentrations because of an affinity that is 10-fold greater than that of potassium ions^{10,30} but is inhibited by thallium at higher concentrations.⁴⁵

Thallium also impairs depolarization of muscle fibers.⁶⁸ Mitochondrial energy is decreased as a result of the inhibition of pyruvate kinase and succinate dehydrogenase, resulting in a decrease of adenosine triphosphate (ATP) generation via oxidative phosphorylation. Enzymatic destruction results in swelling and vacuolization of the mitochondria after exposure to thallium.⁹⁵ At low concentrations, thallium can activate other potassium-dependent enzymes such as phosphatase, homoserine dehydrogenase, vitamin B₁₂-dependent diol dehydrogenase, L-threonine dehydrogenase, and adenosine monophosphate (AMP) deaminase.⁶⁸ The net result of these processes is a failure of energy production.

Thallous ions have been used to isolate riboflavin from milk in the form of a reversible precipitate. Thallous ions may also form insoluble complexes and cause intracellular sequestration of riboflavin in vivo.¹³ Riboflavin is the vitamin precursor of the flavin coenzyme flavin adenine dinucleotide (FAD). Because of a decrease in riboflavin, metabolic reactions dependent on flavoproteins decrease, causing disruption of the electron transport chain and a subsequent further decrease or impairment in the generation of cellular energy.¹³ This decrease in cellular energy may lead to a decrease in mitotic activity and cessation of hair follicle formation, resulting in the clinical sign of alopecia. Subsequent hair loss is the result of combined arrested formation and local destruction of hair shaft cells in the hair bulb^{13,83} (Chap. 18). Unfortunately, riboflavin supplementation was not beneficial in one animal model of thallium poisoning.⁶ Data also demonstrate that the dermatologic, neurologic, and cardiovascular effects of thallium toxicity mirror the manifestations of thiamine deficiency (beriberi), highlighting the inhibitory effect of thallium on glycolytic enzymes.^{13,68} It is unclear whether thiamine administration has any beneficial effect in patients with thallium poisoning.

Thallium has a high affinity for the sulfhydryl groups present in many other enzymes and proteins. Keratin, a structural protein, consists of many cysteine residues that cross-link and form disulfide bonds. These disulfide bonds add strength to keratin. Thallium interferes with the formation of disulfide bonds, which may lead to the development of alopecia and defects in nail growth, resulting in Mees lines.^{33,68,75,88,89} Additionally, the complexation of sulfhydryl groups with thallium results in a decrease in both the production of glutathione and the reduction of oxidized glutathione.^{35,107} This results in oxidative damage²⁸ and the accumulation of lipid peroxides in the brain (which is most prominent in the cerebellum) and appears as dark, pigmented, lipofuscinlike areas.³⁶ The complexity and presumable multifactorial nature of thallium poisoning are again highlighted by the inability of N-acetylcysteine (NAC)-induced augmentation of glutathione stores to protect against toxicity in an animal model.⁶

Thallium also adversely affects protein synthesis in animals by damaging ribosomes, particularly the 60S subunit.⁴³ Although ribosomes are primarily dependent on potassium and magnesium, thallium will be used if present. In an

experimental model, low concentrations of thallium are protective against hypokalemia-induced ribosomal inactivation. As thallium concentrations increase, the protective effects diminish, resulting in progressive destabilization and destruction of the ribosomes. Ribosomal destruction can also be produced by exposure to high potassium concentrations, but usually on the order of 4.5 to 20 times higher than the thallium concentrations necessary to achieve the same effect.⁴³

Pathologic studies of the CNS in patients with thallium poisoning reveal localized areas of edema in the cerebral hemispheres and brainstem. Chromatolytic changes are prominent in neurons of the motor cortex, third nerve nuclei, substantia nigra, and pyramidal cells of the globus pallidus. In chronic exposures, there are signs of edema of the pial and arachnoidal membranes and chromatolysis, swelling, and fatty degeneration in the ganglion cells of the ventral and dorsal horns of the spinal cord.^{8,83}

The peripheral nervous system, which is usually clinically affected before the CNS, develops a diffuse axonopathy in a classic dying back or Wallerian degeneration pattern^{7,8,17,23,64} (Chap. 24). Fragmentation and degeneration of associated myelin sheaths are accompanied by activation of Schwann cells.^{8,12,13} Because thallium affects the longer peripheral fibers—first sensory, then motor, and finally the shorter fibers—toxic effects occur initially in the lower extremities.^{55,74,111}

CLINICAL MANIFESTATIONS

Many of the effects of thallium poisoning are nonspecific and occur over a variable time course.⁵³ When combined, however, a clear toxic syndrome can be defined (Table 102–1). Alopecia and a painful ascending peripheral neuropathy are the most characteristic findings.^{7,27,67,74} Because of the delayed development of alopecia, the diagnosis of thallotoxicosis is often delayed. In fact, with acute exposures, a dose-dependent latent period of hours to days may precede initial symptoms.^{53,68} When death occurs, it is usually the result of coma with loss of airway protective reflexes, respiratory paralysis, and cardiac arrest.

TABLE 102–1. Clinical Manifestations of Thallium Poisoning

Organ System	Onset of Effects			Residual Effects
	Immediate (<6 hours)	Intermediate (Rarely in the first few days; within 2 weeks)	Late (>2 weeks)	
Gastrointestinal				
Nausea	†			
Vomiting	†			
Diarrhea	†			
Constipation	†	†		
Cardiovascular				
Nonspecific ECG changes	†	†		
Hypertension		†		
Tachycardia		†		
Respiratory				
Pleuritic chest pain	†	†		
Respiratory depression		†	†	
Renal				
Albuminuria		†		
Acute kidney injury		†		†
Dermatologic				
Dry skin		†		
Alopecia		†		†
Mees lines			†	†
Neurologic				
Painful ascending sensory neuropathy		†	†	†
Motor neuropathy		†	†	†
Cranial nerve abnormalities		†		
Delirium, psychosis, coma		†		†
Memory and cognitive deficits			†	†
Optic neuritis	†	†		†

† = Typical onset of symptoms. The time course outlined above may be accelerated with extremely large doses. When † appears in two adjacent columns, the time course is highly variable and may be dose dependent. With small ingestions, many of the effects listed above may not be evident. ‡ = Effects that may persist long after exposure, possibly permanently.

Unlike most other metal salt poisonings, diarrhea is often modest or even absent in thallium toxicity.¹⁵ The most common symptom is abdominal pain, which may be accompanied by vomiting and either diarrhea or constipation.^{21,50,53,65,88,108,109} Constipation may be a result of decreased intestinal motility and peristalsis caused by direct involvement of the vagus nerve.^{15,68} Rarely, severe symptoms occur, such as hematemesis, bloody diarrhea, or ulceration of the mucosal lining.

Pleuritic chest pain was described in a small series of poisoned patients.⁶² Another patient was reported to have developed “chest tightness” shortly after drinking thallium-poisoned tea.⁶⁷ The etiology for this finding is uncertain, although it may also relate to involvement of the vagus nerve.

Tachycardia and hypertension frequently occur in patients with thallotoxicosis and usually develop during the first or second week after acute ingestion. A poor prognosis may be associated with a persistent and pronounced tachycardia. No exact mechanism has been determined for these cardiovascular effects of thallium toxicity. Some authors theorize that they result from autonomic neuropathic dysfunction directly related to involvement of the vagus nerve,⁷⁴ but others have noted early electrocardiographic (ECG) changes, such as prolongation of the QT interval, T wave flattening or inversion, and nonspecific ST segment abnormalities, which might suggest direct myocardial injury.^{8,12,65,68,85} Another theory suggests that the direct stimulation of ATPase in the chromaffin cells by thallium may lead to increased output of catecholamines, resulting in sinus tachycardia.^{5,67}

Neurologic symptoms usually appear 2 to 5 days after exposure. Patients may develop severely painful, rapidly

progressive, ascending peripheral neuropathies.^{7,8,23,62} Pain and paresthesias are present in the lower extremities (especially the soles of the feet), and although numbness is present in the fingers and toes, there is also decreased sensation to pinprick, touch, temperature, vibration, and proprioception.^{7,91} The weight of bedsheets on the lower extremities may be sufficient to cause excruciating pain.^{62,64} Motor weakness is always distal in distribution, with the lower limbs more affected than the upper limbs.^{12,68}

Symptoms of confusion, delirium, psychosis, hallucinations, seizures, headache, insomnia, anxiety, tremor, ataxia, and choreoathetosis are common. The onset of these symptoms is variable and most likely dependent on dose. Ataxia may develop within 48 hours after ingestion. Insomnia occurs in most patients and may progress to total reversal of sleep rhythms. Coma may occur, especially with larger exposures.^{12,53,68,88} All cranial nerves can probably be affected by thallium, although abnormalities of cranial nerves I, V, and VIII have not been reported. Cranial nerve III involvement, as evidenced by ptosis, is common and may be asymmetric.¹² Nystagmus, another common finding, demonstrates involvement of cranial nerves IV and VI.¹² Cognitive abnormalities may persist for months after exposure.⁵⁹

Thallium is toxic to both the retinal fibers and the neural retina.⁹² In cases of a large, single ingestion of thallium, approximately 25% of patients may develop severe lesions of the optic nerve.^{68,88} Optic neuropathy may lead to optic atrophy and a permanent decrease in visual acuity. In the early stages, the optic disk shows signs of neuritis, which is red and poorly defined, and later develops pallor from resultant optic nerve atrophy. In patients exposed to multiple small doses, nearly 100% suffer optic nerve injury.⁶⁵ Visual complaints may be delayed in comparison to other neurologic findings⁹² and may include decreased acuity and central scotomata. Other described ophthalmic effects are noninflammatory keratitis, cataracts, and the color vision defect of tritanomaly (blue color defect).^{99,100}

Kidney function may remain normal in mild cases of thallium poisoning, even though the kidney has greater bioaccumulation than any other organ. Changes in kidney function in patients with severe thallotoxicosis include oliguria, diminished creatinine clearance, elevated blood urea nitrogen, and albuminuria.^{5,62,65,68} These findings correlate with morphologic studies in thallium poisoned rats, demonstrating abnormalities in the renal medulla, mainly in the thick ascending limb of the loop of Henle, that occur by the second day after exposure and resolve by the tenth day.⁵

Alopecia is the most common and classic manifestation of thallium toxicity.^{67,103} Typically occurring as the presenting symptom in patients with chronic exposures after an acute exposure, hair loss begins in approximately 10 days and is maximal within 1 month.^{27,67,71} Facial and axillary hair, especially the inner third of the eyebrows, may be spared, but in some cases, full beards, as well as all scalp hair, are lost.⁸³ Microscopic inspection of the hair reveals a diagnostic pattern of black pigmentation of the hair roots of the scalp in approximately 95% of poisoned patients,^{11,67,88,103} which can be found within 3 to 5 days of initial exposure^{11,65} (Fig. 102–1). In patients with recurrent exposures, several bands may be noted on the hair shaft, demonstrating multiple exposures. Initial hair regrowth is very fine and unpigmented but usually returns to normal after mild exposure.⁶⁵ In patients with severe exposures, alopecia may be permanent. Other dermatologic effects that are observed include acne, palmar erythema, and dry scaly skin that results from sebaceous gland damage.¹⁰³ Mees lines appear within 2 to 4 weeks after exposure^{67,75,88} (Fig. 89–4).

FIGURE 102–1. Hair from a patient with severe thallium poisoning (top) compared to a normal (bottom). Note the dark pigmented granules around the root of the poisoned patient. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Other less common findings include hepatotoxicity,⁴⁴ hypochloremic metabolic acidosis,⁸⁸ anemia, and thrombocytopenia.^{54,88}

Teratogenicity

In animal models, thallium is teratogenic.^{32,34} In humans, one study evaluated 297 children born in a region in which the population's urine thallium concentrations were higher than normal because of industrial contamination of their environment.²² Urine thallium concentrations in the exposed children were as high as 76.5 µg/L. Although these children had a slightly higher than expected incidence of congenital abnormalities, no causal relationship could be established with regard to thallium exposure.²²

There are few human reports of acute thallium poisoning during pregnancy. A comprehensive literature review demonstrated 25 cases, which included acute and chronic exposures that occurred during all trimesters.³⁹ Thallium slowly traverses the placenta and is able to cause characteristic fetal toxicity,^{24,73} which manifests initially as decreased fetal movement, possibly as a consequence of fetal paralysis. The classic clinical signs and symptoms of thallium poisoning are described both in the fetus after abortion and in neonate after viable delivery.^{24,65,73,81} However, the outcome of the pregnancy may be normal despite significant maternal toxicity.^{24,46} The only consistent finding is a trend toward prematurity and low birth weight, especially in children exposed during the first trimester.³⁹ One author recommends continuing the pregnancy as long as the mother is clinically improving.²⁴ It is reasonable to conclude that a fetus exposed to thallium during organogenesis has the potential for permanent injury. Those exposed later in pregnancy may recover without deficit if their exposures are limited and the mother recovers. If the exposure occurs closer to term, the child may be born with overt toxicity such as alopecia, dermatitis, nail growth disturbances, and permanent CNS injury.⁶⁵

These few case reports and animal studies provide confusing and sometimes contradictory results. It seems that fetal outcome is determined by both the trimester of pregnancy and the extent of maternal toxicity. However, because there are insufficient data to predict the outcome of pregnancy complicated by maternal thallium poisoning, no specific course of action can be recommended other than extensive fetal monitoring and aggressive treatment for the mother. When a viable child is delivered, it is important to note that thallium is eliminated in breast milk, and that ongoing evaluation of maternal toxicity is essential because nursing may result in continued exposure for the child.³⁷

ASSESSMENT

Most patients with acute thallium toxicity seek health care soon after exposure because of either alterations in their GI, cardiovascular, and neurologic function. Establishing the correct diagnosis at this early stage is essential to assure a satisfactory outcome. Unfortunately, many patients with either smaller acute exposures or chronic thallium poisoning first present days to weeks after their initial exposure and diagnosis is often further delayed. In these instances, many valuable epidemiologic aspects of the exposure history may be difficult to obtain. GI symptoms may not have occurred or their consequence or etiology may have gone unrecognized because of their nonspecific, mild, and transient nature. Many patients with small acute or chronic exposures usually seek care because of alopecia or neuropathy.

The differential diagnosis of the neuropathy includes poisoning by arsenic, colchicine, vinca alkaloids, and disorders such as botulism, thiamine deficiency, and Guillain-Barré syndrome. Both the sensory neuropathy and the preservation of reflexes help differentiate thallium-induced neuropathy from Guillain-Barré syndrome and most other causes of acute neuropathy.¹² When GI symptoms are present in addition to a neuropathy and other end-organ effects, poisoning with metal salts such as arsenic and mercury should be considered (**Chaps. 89 and 98**). The differential diagnosis of rapid onset alopecia is more restricted and includes arsenic, selenium, colchicine, and vinca alkaloid poisoning (**Chap. 18**). When present, Mees lines indicate past exposure to metals, mitotic inhibitors, or antimetabolites and as such are nonspecific for thallium poisoning (**Chaps. 18, 89, and 98**).

Diagnostic Testing

Radiographs of tampered food products⁶² or of the abdomen³³ can document the presence of a metal such as thallium, which is radiopaque. Although abdominal radiography may be useful shortly after a suspected exposure, the sensitivity and specificity of this test is unknown. Similarly, the yield from other routine studies, such as the complete blood count, electrolytes, urinalysis, and ECG, is limited in that these other studies are often normal or at most, merely demonstrate nonspecific abnormalities. Although microscopic inspection of the hair is intriguing, this test is unlikely to be conclusive for inexperienced observers.

The definitive clinical diagnosis of thallium poisoning can only be established by demonstrating elevated thallium concentrations in various body fluids or organs. Thallium can be recovered in the hair, nails, feces, saliva, CSF, blood, and urine, and standard assays and normal concentrations for most of these sources can be found.⁶⁸ Qualitative point of care urine spot tests notoriously give false negative results and require the use of dangerous chemicals that are not routinely

available (20% nitric acid) and therefore should be avoided.⁸⁸ The standard toxicologic testing method is to assay a 24 hour urine sample for thallium by atomic absorption spectroscopy.^{16,110} Normal urine concentrations are below 5 µg/L. Some authors suggest a potassium mobilization test to enhance urinary elimination, similar to the ethylenediaminetetraacetic acid (EDTA) mobilization test, to assist in the diagnosis of thallium exposure.^{11,44,88} We advise against this practice because of its lack of proven usefulness and its potential to exacerbate neurologic toxicity (see Potassium below).

MANAGEMENT

The treatment goals for a patient with thallium poisoning are initial stabilization, prevention of absorption, and enhanced elimination. After the initial assessment and stabilization of the patient's airway, breathing, and circulatory status, GI decontamination should be instituted in all patients with suspected thallium ingestions because of the morbidity and mortality associated with a significant exposure.

Decontamination

Patients who present within 1 to 2 hours after ingestion should be considered candidates for orogastric lavage ([Chap. 8](#)). If the patient presents more than 2 hours after ingestion or has had considerable spontaneous emesis, gastric emptying is unnecessary.

Thallium salts are substantially adsorbed to activated charcoal (AC) in vitro.^{41,50} Additionally, because thallium undergoes enterohepatic recirculation, AC may be useful both to prevent absorption after a recent ingestion and to enhance elimination of thallium in patients who present in the post-absorptive phase.¹⁰¹ In fact, a rat model of thallium poisoning demonstrated that multiple-dose AC (given as 0.5 g/kg twice daily for 5 days) increased the fecal elimination of thallium by 82% and substantially improved survival.⁵⁶ Other data demonstrate that AC alone is superior to either forced diuresis or potassium chloride therapy.⁵¹

In patients with severe thallium toxicity, constipation is common, so the addition of oral mannitol^{58,96,108} or another cathartic to the first dose of AC is appropriate. Although no studies address the efficacy of whole-bowel irrigation with polyethylene glycol electrolyte lavage solution, this technique may prove useful, especially when radiopaque material is demonstrated in the GI tract ([Antidotes in Depth: A2](#)).

Potassium

The similarities between the cellular handling of potassium ions and thallium ions led to the investigation of a possible role for potassium in the treatment of thallium poisoning. In humans, potassium administration is associated with an increase in urinary thallium elimination.^{15,29,76} The magnitude of this increase is reported to be on the order of two-to threefold.⁷⁶ This is supported by animal models that demonstrate some benefit in terms of either enhanced thallium elimination or animal survival.^{30,51,56} Potassium administration is believed to both block tubular reabsorption of thallium and mobilize thallium from tissue stores, thereby increasing thallium concentrations available for glomerular filtration.^{70,88} However, the mobilization of the thallium is of concern. Many authors report either the development of acute neurologic toxicity or the significant exacerbation of neurologic symptoms during potassium administration.^{7,29,62,76,85,104} Others cite data demonstrating that the augmentation of thallium elimination by potassium administration in humans is quite limited.⁴⁹ Additionally, animal models demonstrate that potassium loading enhances lethality⁶¹ and permits thallium redistribution into the CNS.³⁶ For these reasons, the routine use of potassium should be considered potentially dangerous. Some authors recommend forced diuresis, especially in conjunction with potassium chloride.^{20,101} However, no convincing experimental or clinical evidence can support the use of forced diuresis with or without potassium at this time.

Likewise, the similarities between thallium and potassium might suggest a role for administration of sodium polystyrene sulfonate (SPS) as a sodium–thallium exchange resin. Although in vitro binding between thallium and SPS is excellent, it is unlikely to be clinically useful because of preferential binding between potassium and SPS.⁴¹ Consequently, neither the use of potassium nor of SPS is recommended.

Prussian Blue

Prussian blue is approved by the Food and Drug Administration for thallium toxicity ([Antidotes in Depth: A28](#)).¹⁰² When given orally, Prussian blue acts as an ion exchanger for univalent cations, with its affinity increasing as the ionic radius of the cation increases. As such, Prussian blue interferes with the enterohepatic circulation of thallium by exchanging potassium ions from its lattice for thallium ions in the GI tract. This results in the formation of a concentration gradient, causing an increased movement of thallium into the GI tract.

Humans with thallium poisoning are routinely given Prussian blue, which appears to result in clinical benefits,

enhanced fecal elimination, and decreasing thallium concentrations.^{16,18,62,79,96,104,105,108,109} One series of 11 thallium poisoned patients demonstrated both the safety of Prussian blue and its ability to substantially increase fecal thallium elimination.⁹⁶ Unfortunately, because there have been no controlled trials in humans that compare Prussian blue with other drugs and because many of the patients reported above received multiple therapies, the actual efficacy of Prussian blue is unknown.

The dose of Prussian blue is 250 mg/kg/d orally via a nasogastric tube in two to four divided doses.⁹⁶ For patients who are constipated, the Prussian blue may have greater benefit if dissolved in 50 mL of 15% mannitol.¹⁰¹ Although any cathartic may be useful, most authors have used mannitol, possibly because of concerns regarding repeated use of magnesium containing cathartics in patients with neurologic findings and the use of sorbitol in patients with poor GI mobility. (Other dosing regimens are discussed in Antidotes in Depth: A28.)

Extracorporeal Drug Removal

Extracorporeal drug removal may have a limited beneficial role in patients with thallium toxicity, especially if it is begun shortly after the initial exposure while serum concentrations remain high before effective tissue distribution. Because a frequently quoted review attests to the benefits of hemodialysis,⁶⁵ many patients still receive this therapy.⁶⁴ The actual data, however, show that hemodialysis, at various stages of poisoning, is no better than forced diuresis.^{18,78} Reported thallium removal rates by hemodialysis are trivial: 143 mg of thallium was removed by 120 hours,⁷⁹ 222.8 mg was removed by 121 hours,¹⁸ and 128 mg was removed by 54 hours of hemodialysis.¹⁸ These quantities can be placed in perspective knowing that the minimum lethal adult dose of thallium is estimated to be on the order of 1 g,⁶⁸ and that many reported cases exceed that by a factor of 10. Data from a more recent hemodialysis experience suggest that by using high blood flow rates (300 mL/min), clearances as high as 90 to 150 mL/min could be obtained.⁵⁸ Although these clearances seem encouraging, they should be interpreted with an appreciation of the large volume of distribution that thallium achieves in the post absorptive phase. With lower blood flow rates, charcoal hemoperfusion may be two to three times more efficient than hemodialysis, providing clearance rates as high as 139 mL/min.¹⁸ Combined hemoperfusion and hemodialysis were used in several cases^{4,18,19} and were reported to remove as much as 93 mg of thallium within 3 hours of therapy.⁴ Although extracorporeal therapy alone is probably insufficient for patients with significant poisoning and unnecessary in those with small exposures, it may have some benefit when used in combination with other therapies, especially in patients with either underlying chronic kidney disease or acute kidney injury from thallium poisoning, and those with early massive, and presumed lethal, exposures. As is the case with other xenobiotics, thallium is probably not effectively removed by peritoneal dialysis.⁴⁹ A multidisciplinary consensus work group recently supported extracorporeal therapy in patients with acute poisoning when blood thallium concentrations are greater than 400 µg/L (if rapidly available), or, if in the absence of laboratory support severe signs and symptoms are present and treatment can be initiated within 24 to 48 hours of ingestion.³¹ Table 102–2 summarizes the suggested therapy for thallium poisoned patients.

TABLE 102–2. Treatment for Thallium Poisoning

Early (patients who present in the first 1–2 hours postexposure)

- Stabilize airway, breathing, and circulation if necessary.
- Consider orogastric lavage if the patient has not vomited.
- Consider whole-bowel irrigation with polyethylene glycol electrolyte lavage solution for patients with large ingestions or the presence of radiopaque material on abdominal radiographs.
- Begin multiple-dose activated charcoal therapy (MDAC); add a cathartic (preferably oral mannitol) to the first dose if the patient is constipated. Discontinue MDAC when Prussian blue becomes available.
- Give 250 mg/kg/d of Prussian blue in two or four divided doses dissolved in water or 50 mL of 15% mannitol if the patient is constipated.
- Consider simultaneous charcoal hemoperfusion and hemodialysis, especially if the patient has chronic kidney disease or acute kidney injury.

Late (patients who present more than 24 hours after exposure or with chronic toxicity)

- Stabilize airway, breathing, and circulation if necessary.
- Begin multiple-dose activated charcoal therapy; add a cathartic (preferably oral mannitol) to the first dose if the patient is constipated. Discontinue MDAC when Prussian blue becomes available.
- Give 250 mg/kg/d of Prussian blue in two or four divided doses dissolved in water or 50 mL of 15% mannitol if the

patient is constipated.

Chelation

Patients with thallium toxicity do not respond to traditional chelation therapy. Studies demonstrate that the use of EDTA and diethylenetriamine pentaacetic acid are without benefit.^{68,88} Dimercaprol (British anti-Lewisite {BAL}) and D-penicillamine also fail to enhance thallium excretion in experimental models.^{68,88} In one model in which D-penicillamine was able to enhance thallium elimination, the resultant substantial thallium redistribution into vital organs was a significant disadvantage.⁸⁴ More recently, a rodent model of combined use of Prussian blue with DL-penicillamine not only suggested a survival advantage for combined therapy but demonstrated reduced thallium concentrations in vital organs, including the brain.⁶⁶ Sulfur-containing compounds such as cysteine and NAC are not beneficial.^{56,60} Another chelator, diphenylthiocarbazone (dithizone), forms a minimally toxic complex with thallium, resulting in a 33% increase in fecal elimination of thallium in rats.⁹³ Unfortunately, dithizone is goitrogenic and diabetogenic in animal studies.^{56,69,101} Dithiocarb (sodium diethyldithiocarbamate), an intermediate metabolite of tetraethylthiuram disulfide (disulfiram, or Antabuse) (Chap. 79), also increases the urinary excretion of thallium.^{93,98} Before thallium elimination, however, the formation of a lipophilic thallium–diethyldithiocarbamate complex may result in the redistribution of thallium into the CNS.^{47,98} After decomposition of the chelate complex, thallium may remain in the CNS, potentially exacerbating neurologic symptoms.^{47,86} Because of the significant adverse effects of dithizone and the redistribution of thallium after Dithiocarb use, neither chelator is recommended in the treatment of patients with thallium poisoning.

Currently, there is renewed interest in the water-soluble analogs of BAL (DMPS and succimer). However, in an animal model, DMPS failed to decrease tissue concentrations of thallium.⁶⁹ Similarly, in another animal model, although succimer improved survival over control subjects, the benefit was less than that achieved for Prussian blue and was at the cost of an increase in brain thallium concentrations.⁸⁷ Preliminary animal investigations demonstrate reduction in serum thallium concentrations after administration of the iron chelators deferoxamine and deferasirox.^{26,90} Although worthy of additional study, these results are too preliminary to recommend either antidote in thallium-poisoned patients.

SUMMARY

- Thallium is a multisystem toxin whose effects result from cellular mimicry for potassium and avid binding to sulfhydryl groups.
- The elimination of thallium salts from depilatories and rodenticides has substantially reduced the incidence of both intentional and unintentional thallium toxicity in the United States.
- Cases of significant poisoning still occur in countries where thallium-containing rodenticides remain in use, as well as in this country, from attempted homicide and by personal injury from contamination of foods and illicit xenobiotics.
- Early recognition of the characteristic signs and symptoms of thallium poisoning, such as a painful ascending neuropathy and alopecia, followed by prompt initiation of safe and appropriate therapy will substantially improve the prognosis.
- Patients with acute oral poisonings should receive at least one dose of oral AC followed by either multiple dose activated charcoal (MDAC) or Prussian blue, if available. Oral mannitol can be added to either MDAC or Prussian blue when constipation is present.
- In severe acute poisoning, the addition of hemodialysis or combined hemodialysis and hemoperfusion in series may be beneficial.

A28 ANTIDOTES IN DEPTH

Prussian Blue

Robert S. Hoffman

INTRODUCTION

Poisoning with salts of thallium or cesium are uncommon causes of life-threatening toxicity where supportive care may be insufficient to alter outcome. Radioactive cesium can be released as part of a nuclear incident or dispersed as a “dirty bomb,” producing radiation poisoning with sub-toxic cesium doses. Prussian blue is an orally available cation exchange resin that definitively enhances elimination of thallium and cesium in humans and animals and improves survivability in animals.

HISTORY

Prussian blue, the first artificially synthesized pigment, was discovered unintentionally by Diesbach in 1704 while attempting to make another pigment, cochineal red lake. Although immediately popular in art and later in printing, it took approximately 250 years to recognize that Prussian blue could attract monovalent alkali metals into its crystal lattice. Subsequently, in 1963, Nigrovic demonstrated that Prussian blue enhanced cesium elimination from the gastrointestinal tract of rats given either oral or intraperitoneal cesium.³⁷ In 2003, the US Food and Drug Administration (FDA) approved Prussian blue (Radiogardase) for the treatment of thallium and radioactive cesium poisoning.

The Prussian blue literature is complicated by many confusing chemical and physical terms. The product synthesized by Diesbach, $\text{Fe}_4[\text{Fe}(\text{CN})_6]_3$, commonly known as insoluble Prussian blue, is assigned the Chemical Abstracts Service (CAS) number 14038-43-8 and is the FDA-approved product Radiogardase (Fig. A28–1). Synonyms for Prussian blue include Berlin blue, Hamburg blue, mineral blue, Paris blue, and Pigment blue 27, among others.⁵⁶ These names are often used interchangeably to refer to both insoluble Prussian blue and a soluble (colloidal) Prussian blue that either has the molecular formula $\text{KFe}[\text{Fe}(\text{CN})_6]_3$ or $\text{K}_3\text{Fe}[\text{Fe}(\text{CN})_6]_3$. Thus “Prussian blue” also carries two additional CAS numbers: 25869-98-1 and 12240-15-2.³⁸ Compounds containing the same basic core structure, such as $\text{NH}_4\text{Fe}[\text{Fe}(\text{CN})_6]_3$ (ammonium ferric ferrocyanide or Chinese blue) and sodium ferric ferrocyanide, may have similar efficacy in binding monovalent cations and are also sometimes incorrectly called Prussian blue. For the purpose of clarity, general statements that follow use the term “Prussian blue.” In many instances the terms “insoluble” and “soluble” are chosen to highlight differences between the compounds. Unfortunately, because many studies do not specify which Prussian blue is used, some inherent ambiguity persists in the literature. Radiogardase, the currently available pharmaceutical preparation, is the insoluble form of Prussian blue, possibly selected preferentially for its efficacy in cesium poisoning.

FIGURE A28–1. The chemical structure of insoluble Prussian blue. The Roman numerals II and III denote the valence state of iron. Although in most current nomenclature this would be expressed as Fe^{2+} and Fe^{3+} , the figure is drawn this way for consistency with most available references, which employ the older nomenclature.

PHARMACOLOGY

The crystal lattice of Prussian blue typically binds cationic potassium ions from the surrounding environment. However, because its affinity increases as the ionic radius of the monovalent cation increases, Prussian blue preferentially binds cesium (ionic radius: 1.69 Å) and thallium (ionic radius: 1.47 Å) over potassium (ionic radius: 1.33 Å).^{8,18} Additionally, strong binding for rubidium (ionic radius: 1.48 Å) is demonstrated.⁴⁸ Thus, when given orally, Prussian blue binds unabsorbed thallium or cesium in the gastrointestinal tract, preventing absorption and reversing the concentration gradient to enhance elimination through gastrointestinal dialysis. Prussian blue can also interfere with enterohepatic circulation, causing a further reduction in tissue stores.

Insoluble Prussian blue remains almost exclusively in the gastrointestinal tract and is eliminated nearly entirely in feces at a rate determined by gastrointestinal transit time. In a radiolabeled study of healthy pigs, 99% of a single ingested dose was recovered unchanged in the stool.³³ In contrast, soluble Prussian blue is slightly absorbed based on the clinical finding of a blue discoloration that develops in the sweat and tears of patients undergoing prolonged therapy.¹⁴ This discoloration appears to be without clinical significance and resolves within days when therapy ceases. No significant food or drug interactions are known to exist.

THALLIUM

In Vitro Adsorption

The chemical formulation of Prussian blue influences the in vitro and, presumably, the in vivo adsorption of thallium ions. An early investigation demonstrated that the soluble form more effectively adsorbs thallium than the insoluble form.¹⁰ In a more rigorous study, the in vitro adsorptions of both forms were similar when thallium concentrations remained low.¹⁷ However, as thallium concentrations increased, the colloidal (soluble) form demonstrated far greater adsorptive capacity. Although not proven, this difference may occur because the soluble form contains more potassium and can therefore exchange proportionally more cation. Furthermore, the actual size of the crystal lattice alters its efficacy. Laboratory synthesized Prussian blue (with a crystal size of 176.8 Å) was compared with a commercial preparation (with a crystal size of 311.9 Å). The laboratory synthesized product adsorbed more thallium in vitro because its smaller size increased its surface area.¹⁸ In vitro analysis of the FDA-approved antidote demonstrated that pH and hydration state greatly influenced adsorption, with the maximal adsorptive capacity (MAC) predicted to be as high as 1400 mg of thallium/g at pH 7.5.⁶⁷

In Vitro Comparison of Prussian Blue and Activated Charcoal

In one in vitro study, thallium was well adsorbed to Norit brand activated charcoal.¹⁷ Although numerical data are not supplied in the body of the paper, the 10% to 20% adsorption to activated charcoal demonstrated in a figure was far less than the results achieved with several different forms of Prussian blue tested simultaneously.¹⁷ Two other binding studies showed different results from the Norit activated charcoal study. An early investigation determined that the MAC of activated charcoal was 124 mg of thallium/g, whereas the MAC for Prussian blue was only 72 mg of thallium/g.¹⁹ More recently, a MAC of only 59.7 mg of thallium/g was calculated for CharcoAid activated charcoal, compared with a higher MAC for insoluble Prussian blue of 72.7 mg of thallium/g.¹⁵ Although the MACs for Prussian blue in these two studies are nearly identical, they differ significantly from the MAC reported above for the FDA approved formulation, possibly as a result of different experimental conditions.⁶⁷ Similarly, the variable results for activated charcoal may also be a function of the study pH or the different types of activated charcoal used.

Animal Data: Kinetics, Tissue Concentrations, and Survival

Thallium. Sublethal doses of thallium were used to evaluate the effects of various antidotes in rats over an 8 day period.¹⁹ Although the control group only eliminated 53% of the administered dose of thallium, 93% of the dose was eliminated in the activated charcoal, and 82% was eliminated in the insoluble Prussian blue groups. In contrast, other investigators demonstrated only a modest increase in thallium elimination in rats treated with oral activated charcoal while demonstrating a consistent benefit of Prussian blue.²⁰

Multiple studies demonstrate that Prussian blue not only decreases the half-life of thallium in animals but also lowers thallium content in critical organs such as the brain and the heart.^{13,30,31,47,49} Half-lives are typically reduced by approximately 50% when Prussian blue is given with or without a cathartic. The rationale for the cathartic is that constipation is invariably present in humans and animals with severe thallium poisoning.

Only a few studies evaluate the effects of Prussian blue on survival. In these studies, a statistically significant survival advantage is shown in thallium poisoned rats^{18,49} and mice²⁴ treated with Prussian blue. The experimental benefit is on the order of a 31% increase in the LD₅₀ (median lethal dose for 50% of poisoned animals).⁵⁰ Although most chelators have a

limited or detrimental effect in thallium poisoning (Chap. 102) and DL-penicillamine has no demonstrable benefit as a single antidote, in an animal model the combined use of Prussian blue and DL-penicillamine not only decreased thallium concentration in critical tissues such as the brain but also enhanced survival.²⁸ While interesting, these data are too premature to recommend the routine use of combined DL-penicillamine and Prussian blue in poisoned humans.

Radioactive Thallium. There is no published experience describing human poisoning with radioactive thallium. Prussian blue has demonstrable efficacy in an animal model of radioactive thallium poisoning, as would be expected because the ionic radii of isotopes are generally similar. In one small study, insoluble Prussian blue decreased the biologic half-life of radioactive thallium in rats by approximately 40%.³ Many humans receive radioactive thallium (²⁰¹Tl) chloride as part of myocardial scintigraphy, with a typical adult dose of 110 megabecquerels (MBq). Recent concerns about excess radiation exposure following the termination of diagnostic testing have led to the evaluation of Prussian blue to enhance post-imaging elimination. In vitro evidence suggests a MAC of 5000 MBq/g.² In a controlled trial, where Prussian blue was given to a patient post myocardial scintigraphy, radioactivity was reduced 18% and 30% after 24 and 48 hours, respectively.²

Thallium Poisoning in Humans

A thorough analysis of the efficacy of Prussian blue in thallium poisoning is severely hampered by many factors. First, and most importantly, there are no controlled human trials. Second, although multiple patients have received Prussian blue in the setting of thallium poisoning, many were simultaneously treated with a variety of therapies, including forced potassium diuresis, single-or multiple-dose activated charcoal, and either hemodialysis or hemoperfusion. Thus, it is impossible to determine the specific effects of Prussian blue on morbidity or mortality, and even toxicokinetic data must be interpreted with caution. Third, many reports fail to specify the exact type of Prussian blue used. Those investigations that do specify the type of Prussian blue typically employed the soluble form, which is presently unavailable as a pharmaceutical preparation in the United States. Discussions of the available data in the following sections are limited by these considerations.

Three patients, in 1971, were the first to receive Prussian blue as a treatment for thallium poisoning.¹⁷ Although daily fecal thallium concentrations were not determined in two of the three patients because of severe constipation, an approximately sevenfold increase in fecal thallium elimination over baseline was attributed to Prussian blue therapy in the third patient. Subsequently, many humans with thallium poisoning have received Prussian blue, with or without a cathartic, as part of their therapy.^{1,5,7,8,12,17,41,44,45,53,59,60,64} Unfortunately, other components of therapy that may have confounded the effects of Prussian blue in these cases include single-or multiple-dose activated charcoal and the use of D-penicillamine, dimercaprol, ethylenediaminetetraacetic acid (EDTA), succimer, 2,3-dimercaptopropane-1-sulphate (DMPS), forced potassium diuresis, and either hemodialysis or hemoperfusion. There are no controlled human trials of any of these modalities alone or in combination, and most of the data presented are based on single case reports or small case series.

One of the largest series was comprised of 11 thallium poisoned patients who were treated with soluble Prussian blue.⁵³ This report not only demonstrated the tolerability of Prussian blue, but also was the first to systematically evaluate its fecal elimination. In all individuals studied, fecal elimination remained high, even when urinary elimination fell, suggesting selective redistribution of thallium into the gut.⁵³ Although the authors commented on clinical improvement in these patients, the lack of controlled data makes these subjective observations difficult to interpret. Similarly, a substantial reduction in thallium half-life was demonstrated when Prussian blue was compared with no therapy at all in patients with thallium poisoning.⁸ More recently, a series of 14 patients with delayed presentation (9–19 days) were reported. These patients were treated with DMPS, followed by Prussian blue and hemodialysis, and 13 survived. Data are insufficient to make inferences about the effects of Prussian blue alone or as part of this treatment regimen.⁵⁴

Dosage and Administration

The dosage of Prussian blue has never been investigated systematically in either humans or animals. In most of the case reports and series mentioned above, a total dose of 150 to 250 mg/kg/d was administered orally or via a nasogastric tube in two to four divided doses.⁵³ Because constipation or obstipation is often present or expected, Prussian blue is generally administered dissolved in 50 mL of 15% mannitol.⁵⁵ Although any cathartic may be appropriate, mannitol is used most frequently, possibly because of concerns over the risks associated with repeated doses of magnesium or sorbitol (Antidotes in Depth: A2). The manufacturer of Radiogardase recommends that adults and adolescents with thallium poisoning receive a total dose of 9 g divided daily (3 g every 8 hours) and that children receive a total dose of 3 g divided daily (1 g every 8 hours). Although the manufacturer does not recommend using a cathartic, a high fiber diet is advocated when constipation is present. Because Prussian blue is well tolerated, the editors of this text continue to favor the 150 to 250 mg/kg/d dosing because it provides more antidote with limited adverse consequence, as most of the published experience has used this dose with essentially no adverse effects. In addition, because many severely poisoned patients cannot eat, the use of a cathartic should be considered when constipation is consequential.

The end point of therapy is similarly poorly defined. By convention, Prussian blue is usually continued until urinary thallium concentrations fall below 0.5 mg/d. Although this end point may not be a perfect measurement of thallium burden, as small amounts of fecal elimination continue, even when urinary elimination has diminished,⁵³ most laboratories are not equipped to measure fecal thallium concentrations. In patients who remain significantly symptomatic, Prussian blue therapy could be continued for a short period past the 0.5 mg/d endpoint on an individual basis.

CESIUM

The radioactive isotope of cesium (¹³⁷Cs), a common byproduct of nuclear fission reactions, is a strong β and γ emitter with a physical half-life of more than 30 years and a biologic half-life of about 110 days. Another isotope (¹³⁴Cs) is only produced by neutron activation of the stable isotope (¹³³Cs) and has a physical half-life of about 2 years and a biologic half-life comparable to ¹³⁷Cs. Cesium is absorbed in the small bowel, distributes like potassium, and undergoes enteric recirculation in a manner comparable to thallium.²⁹ Approximately 80% of a given dose of cesium is eliminated in the urine, with 20% cleared in the feces.

The isotope ¹³⁷Cs is used clinically as a radiotherapy source in nuclear medicine and to irradiate banked blood. Although uncommon, radiologic disasters such as Fukushima, Chernobyl, and Goiânia (see Human data below) have resulted in lethal incorporation exposures. Additionally, concerns over the use of ¹³⁷Cs in “dirty bombs” have increased the potential need to treat patients with radioactive cesium poisoning. Toxicity from nonradioactive cesium is also reported. Many cases of QT interval prolongation and torsade de pointes are reported in patients taking cesium chloride either as a dietary supplement or for its alleged antineoplastic effects.^{4,6,22,40,46,51,57}

In Vitro Adsorption

Standard binding studies compared the ability of activated charcoal, sodium polystyrene sulfonate (SPS), and both soluble and insoluble Prussian blue to adsorb ¹³⁷Cs over a range of gastrointestinal pHs.⁶² Unlike thallium, the adsorption of cesium to activated charcoal was negligible. Comparable to thallium, SPS offered no benefit, likely because of preferential effects on potassium. Although both forms of Prussian blue adsorbed cesium, the insoluble form was consistently superior. A pH of 7.5 was selected to represent the pH of the small bowel lumen, the location where most adsorption would occur. At this pH, a MAC of 238 mg of ¹³⁷Cs/g of insoluble Prussian blue was determined. In an interesting extension, when the same authors bound insoluble Prussian blue to a hemoperfusion column, they demonstrated a clearance of approximately 100 mL/min of ¹³⁷Cs from plasma and projected that a 4 hour treatment would adsorb about 0.3 terabecquerel (TBq) of radioactive cesium.⁶³ When the FDA approved antidote was analyzed, like thallium, pH and hydration introduced significant variations in binding, with a MAC of 715 mg of cesium/g noted at pH 7.5.¹¹

Animal Data: Kinetics, Tissue Concentrations, and Survival

Small animal investigations with either ¹³⁴Cs or ¹³⁷Cs consistently demonstrate that Prussian blue therapy reverses the urine-to-stool elimination ratio from 8:1 to 0.3:1 and reduces the biologic half-life and the total body area under the curve by as much as 60%.^{32,36,37,48,52} For example, rats given oral ¹³⁴Cs retained 84.7% of the ingested dose at 7 days. Treatment with insoluble and soluble Prussian blue, as well as Chinese blue, produced significant reductions in retained cesium (only 6.36%, 2.63%, and 2.43% of the dose was retained at 7 days, respectively).⁹

In addition to human toxicity, concern over radioactive cesium incorporation into cattle milk and meat has resulted in a number of large animal model investigations. Daily Prussian blue therapy reduced radioactive cesium concentrations in sheep by as much as 42%.^{16,43} Likewise, radioactive cesium transfer to milk was reduced by 85% in cows.⁵⁸ When dogs were contaminated with ¹³⁷Cs, Prussian blue reduced total body burden by as much as 51%.²⁶ Similar efficacy in reducing the amount of cesium was demonstrated in meat from pigs fed ¹³⁴Cs contaminated whey, with insoluble Prussian blue reducing activity from 359 Bq/kg to 11 Bq/kg over 27 days.⁹

Human Volunteer Studies

Two human volunteers ingested meals contaminated with ¹³⁴Cs to compare the efficacy of both the soluble and insoluble forms of Prussian blue with controls.⁹ At 14 days after exposure and without therapy, the volunteers retained 94.7% of the ingested dose, compared with retention of only 5.1% following therapy with insoluble Prussian blue and 4.9% following soluble Prussian blue. In another study, two volunteers demonstrated that Prussian blue decreased the biologic half-life of ingested radioactive cesium by approximately 33%.²³ Finally, in two volunteers, the effects of pretreatment were compared with simultaneous post-treatment Prussian blue. When a single dose of Prussian blue was administered 10 minutes before ¹³⁴Cs, absorption decreased from 100% (without therapy) to 3% to 10%. However, simultaneous administration of 0.5 or 1

g of Prussian blue with ^{134}Cs resulted in 38% to 63% absorption. Finally, when Prussian blue was given daily at a dose of 0.5 g every 8 hours in the post-absorptive phase, the biologic half-life of ^{134}Cs was reduced from 106 to 44 days.³⁵

Radioactive Cesium Poisoning in Humans

There are no controlled trials of Prussian blue in radioactive cesium poisoning. Experience is derived exclusively from treating disaster victims. In 1987, a number of people in Goiânia, Brazil, were incorporated with radioactive cesium from a discarded radiotherapy unit.³⁹ Although the reported total number of individuals treated is uncertain because of multiple reports that probably include the same patient several times, one group describes 37 patients who were given insoluble Prussian blue in doses ranging from 3 g/d in children up to 10 g/d in adults. Untreated, elimination kinetics were first order, and half-lives varied extensively from 39 to 106 days in adults (mean: 65.5 days in women and 83 days in men). Half-lives were shorter in children. Therapy with insoluble Prussian blue reduced half-lives by a mean of 32%,²¹ and reduced the retained cesium dose from between 51% and 84% of the total dose.²⁵

The nuclear disaster at Chernobyl, Ukraine, resulted in many cases of acute radiation exposure as well as incorporation into the population of radioactive iodine, cesium, and strontium. In one trial, insoluble Prussian blue was given to three victims of radioactive cesium incorporation many weeks after their exposure. The reported reduction in biologic half-life ranged from 12% to 52%.²⁷ The authors of this paper include data from the Chinese literature describing another six patients who demonstrated a similar reduction in the biologic half-life of cesium following Prussian blue therapy.

Non-Radioactive Cesium Poisoning in Humans

Two cases describe the use of Prussian blue for patients with non-radioactive cesium poisoning. A 58 year-old woman presented with syncope, polymorphic ventricular tachycardia, hypokalemia, and a QT interval of 590 msec after taking cesium chloride as an alternative therapy for cancer. The apparent half-life of cesium was reported as 7.9 days during Prussian blue therapy in comparison to 86.6 days after therapy. The authors state that there were no adverse effects of therapy.⁵⁷ Similarly, a 65 year-old woman presented with syncope and was found to have multiple episodes of torsade de pointes, hypokalemia, and a QT interval of 620 msec after taking cesium chloride for 6 weeks. Therapy with insoluble Prussian blue (3 g/d) was associated with a reduction in the apparent half-life for cesium from 61.7 to 29.4 days.⁴

Dosage and Administration

The manufacturer of Radiogardase recommends that for radioactive cesium poisoning, adults and adolescents 13 years or older receive a total daily dose of 9 g divided into 3 g, three times per day. Children aged two through twelve years should receive a total daily dose of 3 g divided into 1 g, three times per day. While the manufacturer offers no recommendation in children under the age of two years, administering 150 to 250 mg/kg/d in divided doses would be appropriate. Although these are the same doses used for thallium poisoning, therapy for cesium poisoning should be continued for at least 30 days. Even though there are no recommendations of other criteria to determine the end point of therapy, quantitative and radiologic evaluations of cesium elimination should be performed. Capsules can be opened and mixed in liquids and given via nasogastric tube for patients unable to swallow. Since constipation does not commonly occur with either radioactive or non-radioactive cesium poisoning, neither routine cathartic administration nor the use of a high fiber diet is recommended.

ADVERSE EFFECTS AND SAFETY ISSUES

Animal studies show no adverse effects of therapeutic doses.⁴² Oral lethal doses are not known or projected for humans, but are likely to be astronomic given that there is no or minimal absorption of Prussian blue and the absence of local toxicity in the GI tract. The only significant adverse effects reported in humans receiving therapeutic doses are constipation and hypokalemia,⁵⁵ and the constipation may be related more to the thallium toxicity than to Prussian blue.

Although there is some concern regarding the potential for cyanide liberation from Prussian blue, this release appears to be quantitatively minimal. Cyanide release from soluble Prussian blue was less than 3 mg/24 h in simulated gastric fluid.⁶¹ When three human volunteers were given 500 mg of soluble Prussian blue (radiolabeled with ^{59}Fe , either in the ferric or ferrous position and with ^{14}C on the CN), only 2 mg of cyanide were absorbed.³⁴ Over the physiological range of potential gastrointestinal pH, the maximal cyanide release from insoluble Prussian blue is only 135 $\mu\text{g/g}$ at pH 1.^{65,66} When extrapolated even for repeated therapeutic doses, only a trivial amount of cyanide would be liberated.

PREGNANCY AND LACTATION

Insoluble Prussian blue is listed as pregnancy category C. Because of the severe consequences of poisoning from radioactive cesium and thallium, and the lack of systemic absorption of insoluble Prussian blue, a risk-to-benefit analysis

would favor the use of the antidote in all poisoned pregnant patients.

FORMULATION AND ACQUISITION

Insoluble Prussian blue (Radiogardase) is available as a 0.5 g blue powder in gelatin capsules for oral administration manufactured from Haupt Pharma Berlin GmbH for distribution by HEYL Chemisch-pharmazeutische Fabrik GmbH & Co. KG, Berlin (281-395-7040; fax 281-395-2320; see information at www.heytext.com). Prussian blue is part of the US Strategic National Stockpile, which can be accessed at CDC emergency response hotline: 770-488-7100; and is also stored at REAC/TS, Oak Ridge: emergency number 865-576-1005. Thirty capsules retail for about \$100 and have a 5 year shelf life.

SUMMARY

- Prussian blue is a crystalline lattice that adsorbs radioactive and non-radioactive isotopes of thallium and cesium.
- Animal data demonstrate the ability of Prussian blue to prevent absorption, enhance elimination, and improve survival following thallium or cesium administration.
- Although human data are limited, the use of Prussian blue appears beneficial in case reports and small case series.
- Since Prussian blue is essentially non-toxic, it should be used whenever severe thallium or cesium poisoning is suspected.
- If Prussian blue is unavailable, activated charcoal can be substituted for thallium poisoning, but not for cesium poisoning.

Zinc (Zn)	
Atomic number	= 30
Atomic weight	= 65.37 Da
Normal concentrations	
Blood	= $800 \pm 200 \mu\text{g/dL}$ ($122 \pm 31 \mu\text{mol/L}$)
Serum	= $109\text{--}130 \mu\text{g/dL}$ ($17\text{--}20 \mu\text{mol/L}$)
Urine (24 hour)	= $<500 \mu\text{g/d}$ ($76.5 \mu\text{mol}$)

HISTORY AND EPIDEMIOLOGY

The Babylonians used zinc alloys more than 5000 years ago,² and references to zinc oxide as a lotion to heal lesions around the eye can be found in the Ebers papyrus, written in 1500 b.c.¹⁸ Zinc oxide and zinc sulfate were used in Western Europe during the late 1700s and early 1800s for gleet (urethral discharge), vaginal exudates, and convulsions. In the late 1800s, brass workers who inhaled zinc oxide fumes were noted to develop “zinc fever,” “brass founders’ ague,” and “smelter shakes,” all of which are now identified as metal fume fever (Chap. 124).⁷⁰

Throughout history, humans have contaminated the environment with zinc. For example, release of zinc from mines elevates concentrations in the local water supply and vegetation, which may lead to elevated tissue zinc concentrations and clinical effects in the nearby population.^{54,64}

The antiinflammatory effects of zinc sulfate were studied in the late 1970s for acne vulgaris with mixed results. However, a double-blinded controlled study found no difference between zinc and placebo.⁷⁵ The more recent use of zinc supplementation as an alternative preventive and treatment strategy for upper respiratory infections is exposing large numbers of patients to undefined risks for unclear benefits.

In more recent history, an epidemic of hematologic and, more importantly, neurologic impairment due to large unintentional exposures to zinc via denture cream was reported. This syndrome sometimes referred to as “Zinc swayback” is further described below.^{3,11,42,58}

CHEMISTRY

Zinc, a transition metal, has two common oxidation states, Zn^0 (elemental or metallic) and Zn^{2+} . The pure element exists as a blue to white shiny metal, but it also combines with other elements to form many compounds: zinc chloride (ZnCl_2), zinc oxide (ZnO), zinc sulfate (ZnSO_4), and zinc sulfide (ZnS). Once the metal is exposed to moisture, it becomes coated with zinc oxide or carbonate (ZnCO_3).⁸⁵

Like the other transition metals iron (Chap. 46) and copper (Chap. 95), zinc ions participate in reactions that result in the generation of reactive oxygen species such as superoxide radicals or hydroxyl radicals which can damage both local and remote tissues (Chap. 12).

PHARMACOLOGY AND PHYSIOLOGY

Zinc is an essential nutrient and found in more than 200 metalloenzymes, including acid phosphatase, alkaline phosphatase, alcohol dehydrogenase, carbonic anhydrase, superoxide dismutase, and DNA and RNA polymerases.⁸⁵ The average daily intake of zinc in the United States is 5.2 to 16.2 mg; foods that contain zinc include leafy vegetables (2 ppm), meats, fish, and poultry (29 ppm).⁸⁵ The recommended daily allowance is 11 mg/d for men and 8 mg/d for women. Pregnant and nursing women require 12 mg/d. Zinc accumulates in erythrocytes resulting in whole blood concentrations six to sevenfold higher than those in the serum.⁷² Zinc and copper concentrations generally have an inverse relationship in the serum with

elevated zinc concentrations resulting in decreased copper concentrations ([Chap. 95](#)).

Zinc contributes to gene expression and chelates with either cysteine or histidine in a tetrahedral configuration, forming looped structures known as “zinc fingers”, which bind to specific DNA regions.^{12,105} Other functions of zinc include membrane stabilization, vitamin A metabolism, and the development and maintenance of the nervous system. Zinc is considered important for fetal growth. When 29 pregnant mothers who were at risk for small for gestational age babies were given zinc citrate, zinc sulfate, or zinc aspartate, no intrauterine growth retardation was observed.⁹¹ Subsequent studies demonstrate that zinc supplementation in women with low serum zinc concentrations in early pregnancy is associated with greater infant birth weights and head circumferences.³⁷ No adverse reproductive effects were observed in a rodent model exposed to inhalational zinc oxide.⁶⁷

Zinc is important in maintaining olfactory and gustatory function ([Chap. 26](#)). Serum, urine, and salivary zinc concentrations are lower in patients with dysfunctional senses of smell or taste. This is thought to be related to an abnormality in a salivary growth factor known as gustin/carbonic anhydrase VI.⁴³ Because this enzyme is zinc dependent, oral zinc may produce subjective improvement in taste and smell in patients with a known decrease in parotid gustin/carbonic anhydrase VI complex.⁴⁴ Oral zinc sulfate also improved subjective findings in a group of 25 patients with post-traumatic olfactory disorders.⁶

Zinc gluconate supplementation when added to corticosteroid therapy was beneficial in patients with sudden sensorineural hearing loss when compared to corticosteroid treatment alone. The antioxidant and antiinflammatory affect on the cochlea is thought to be the mechanism for this benefit.¹⁰⁷

The role of zinc in the immune system is undefined. Zinc as a treatment for non-specific infectious diarrhea remains controversial.⁸⁰ However, it appears to be beneficial specifically in the management of *Shigella* spp by improving the shigellacidal antibody response and increasing circulating B lymphocyte and plasma cells.^{82,83}

Zinc gluconate and zinc acetate containing lozenges are sold as dietary supplements with conflicting evidence that they can shorten the duration of the “common cold.”^{50,66} One placebo-controlled study found that zinc nasal gel shortened the duration of viral syndromes when applied within 24 hours of the onset of symptoms.⁴⁵ A recent systematic review of the current literature concluded that zinc administration within 24 hours of onset of symptoms reduces the duration and severity of the common cold in healthy people. In addition, when supplemented for at least 5 months, it reduces cold incidence, school absenteeism, and prescription of antibiotics in children.⁹²

Zinc deficiency, or hypozincemia, is a well described clinical entity. It can be either inherited as an autosomal recessive pattern known as acrodermatitis enteropathica, or developed due to a defect in zinc absorption in the GI tract.⁷⁷ Those patients at risk for acquiring the disorder include patients who receive total parenteral nutrition without adequate zinc supplementation, patients who have undergone intestinal bypass procedures, those with Crohn disease, and premature infants with low zinc storage. A nationwide shortage of injectable zinc resulted in the development of dermatitis in the diaper region, perioral erosions, and bullae on the dorsal surfaces of the hands and feet in premature infants requiring parenteral nutrition due to severe cholestasis.¹ Excessive ingestion of phytates found in whole grains, legumes, nuts, and seeds may decrease zinc absorption.⁴⁰ Physical findings that suggest the diagnosis of zinc deficiency, regardless of etiology, include the triad of dermatitis (acral and perioral), diarrhea, and alopecia. Zinc salts in initial doses of 5 to 10 mg/kg/d of elemental zinc followed by maintenance doses of 1 to 2 mg/kg/d are highly effective. In fact, skin lesions typically heal within 2 to 4 weeks, and hair growth also restarts during this time frame.

The FDA approved zinc acetate in 1997 for maintenance therapy of Wilson disease, a disorder associated with copper overload.^{13,63} Its use in this disorder is related to the ability of zinc to induce the formation of metallothionein, which assists in the elimination of copper from the blood and body tissues ([Chap. 95](#)).⁷

TOXICOKINETICS AND PATHOPHYSIOLOGY

When ingested, the main site of zinc absorption is the jejunum, although absorption is reported to occur throughout the intestine by binding to metallothionein which is a zinc protein complex in the luminal cells.¹⁰⁴ Metallothionein is a family of specific metal binding proteins with diverse and complex functions considered essential to metal homeostasis. Metallothioneins are of low molecular weight (3500–14,000 Da) and are rich in thiol ligands; it is these ligands that allow high affinity binding to metals such as zinc, copper, cadmium, mercury, and silver. Metallothioneins essentially regulate the peripheral utilization of zinc and copper once they have been bound.³³ Excess zinc absorption leads to upregulation of metallothioneins as a counter regulatory mechanism to prevent excess plasma absorption. However, the affinity of other metals, especially copper, is higher for metallothionein, resulting in excessive copper elimination and hence decreased absorption. The primary route of excretion of the copper and zinc metallothionein complexes is fecal. In addition, sequestration of copper in the absorptive cells of the enterocytes may also play a role in the decreased peripheral utilization of copper.²⁴ Very little metallothionein is bound to zinc or copper in the blood as it is primarily an intracellular

cytosolic molecule.⁸ Albumin binds about two thirds of zinc in the plasma, and the remainder is bound to α_2 -globulins.⁸⁵ Zinc concentrations in the body show a great variability by organ, with the prostate having the highest amount due to its high concentration of the zinc-containing enzyme acid phosphatase.⁹

Zinc salts are used to enhance the solubility of pharmaceuticals such as insulin. Certain salts, such as zinc oxide, are used in baby powder, sun blocks, and topical burn preparations, and may be used on both latex and latex-free gloves. However, the use of oral zinc salts within 3 hours of cephalexin administration decreased peak serum concentrations, which is suggested to result from its inhibitory effects on intestinal transport peptides. The absorption of all β -lactam antibiotics may be altered as they are all dependent on these intestinal transport peptides.²⁶

CLINICAL MANIFESTATIONS

The toxicity of zinc is dependent on the route of exposure. Each zinc compound has similar toxic manifestations following oral and dermal exposure. However, they have unique inhalational toxicities. The metallic form of zinc is not toxic per se, and only the salt forms are considered here unless otherwise specifically mentioned.

Acute

The hallmark of acute oral zinc (Zn^{2+}) toxicity is gastrointestinal (GI) distress, including nausea, vomiting, abdominal pain, and gastrointestinal hemorrhage.⁹ In initial studies that evaluated the oral use of zinc sulfate (ZnSO_4) as an acne therapy, epigastric distress was noted in 33% of patients.^{28,36} Zinc chloride solutions in concentrations greater than 20% are particularly corrosive when ingested. Partial- and full-thickness burns to the oral mucosa, pharynx, esophagus, and stomach, as well as to the laryngotracheal tree, can occur even following small unintentional ingestions of zinc chloride by children.^{22,56,71} Delayed gastric stricture may occur after acute⁷¹ or chronic zinc chloride consumption.^{20,98} Pancreatitis was noted in a piglet model³⁴ and also in a 24 year-old man who inadvertently ingested liquid zinc chloride.²²

Hyperamylasemia, acute respiratory distress syndrome (ARDS), hypotension, vomiting, diarrhea, jaundice, anemia, thrombocytopenia, and subsequent death occurred following an unintentional intravenous infusion of 7.4 g of zinc sulfate (via total parenteral nutrition) over 60 hours. The patient's serum zinc concentration was 4184 $\mu\text{g/dL}$.¹³ A 14 week premature neonate received a 1000 fold increased concentration of zinc in her total parenteral nutrition. Rather than 330 $\mu\text{g/dL}$, she received 330 mg/dL, which resulted in hypotension, respiratory failure, and death despite the administration of CaNa_2EDTA .³⁸

Inhalational toxicity will often depend on the type of zinc compound involved in the exposure. The water solubility of the various zinc salts plays an important role in the extent and time to onset of pulmonary toxicity. The solubility of zinc chloride in water at 77°F (25°C) is 432 g/100 mL, whereas that of zinc oxide at 84°F (29°C) is 0.00016 g/100 mL.⁸⁵ Acute inhalation of zinc chloride from smoke bombs produces lacrimation, rhinitis, dyspnea, stridor, and retrosternal chest pain. Upper respiratory tract inflammation, and ARDS may occur, generally without renal or hepatic manifestations of systemic absorption.^{35,47,48,68} Morbidity and mortality increase when the exposure to a zinc chloride smoke bomb occurs in an enclosed space.⁸⁸ Of 70 individuals exposed to a zinc chloride smoke bomb in a tunnel during World War II, 10 died within 4 days. Ambient zinc concentrations in the tunnel were measured at 33,000 mg/m.^{3,30} Inhalation of zinc oxide, a far less water soluble zinc salt, is associated with metal fume fever ([Chap. 124](#)) and not pneumonitis or ARDS despite similar ambient zinc concentrations.⁹ See below for further discussion on metal fume fever.

Despite the importance of zinc in gustatory function, there appears to be an association of intranasal zinc use and anosmia.⁹³ Animal research suggests that intranasal zinc sulfate use can cause transient or persistent anosmia as a consequence of disruption of functional connections between the olfactory bulb and the olfactory epithelium.⁶⁹ Topical zinc sulfate is used experimentally in both rat and mouse models to induce anosmia.¹⁰² Multiple patients, ages 31 to 55 years, who developed a burning sensation after intranasal zinc gluconate application to the olfactory epithelium later developed either a long lasting or permanent anosmia and olfactory dysfunction.⁵³ The mechanism of zinc-induced hyposmia and anosmia is thought to be a direct result of proteolytic destruction of the olfactory receptor cells.²⁵

US pennies (91.5% Zn and 2.5% Cu) lodged in the distal esophagus release zinc ions following exposure to gastric acids and can damage the local esophageal tissue.¹⁷ The phenomenon of acid dissolution is demonstrated in animal⁴ and in vitro models.⁷⁴

Rare reports of renal complications exist. Hematuria was observed in a 24 year-old man who ingested liquid zinc chloride but whose kidney function remained otherwise normal.²² Intravenous zinc sulfate administration can result in acute tubular necrosis and acute kidney injury.¹³

Certain zinc salts, such as zinc oxide, found in baby powders and calamine lotion, are usually nonirritating for intact skin.⁵ Although older studies suggested the possibility of pruritic, pustular rashes in workers who are exposed to zinc

oxide, other causative factors, including personal hygiene, were not considered.¹⁰⁰ One case report describes urticaria and angioedema in a 34 year-old welder following contact with zinc oxides fumes at a smelting plant.³¹ The patient was asymptomatic once he was removed from the environment and had no further difficulty during the welding process when personal protective equipment was employed.

Chronic

Several individual cases report the significant implication of chronic zinc exposure. Chronic zinc toxicity following nutritional supplements and the ingestion of coins can produce a reversible sideroblastic anemia manifested by anemia and granulocytopenia associated with bone marrow-demonstrated vacuolated precursors and ringed sideroblasts.¹⁴ The mechanism for this reversible myelodysplastic syndrome appears to be a zinc-induced copper deficiency.³²

A 55 year-old schizophrenic patient with a 15 year history of pica typically of metal objects and frequently zinc containing pennies, presented with pancytopenia, including a hemoglobin of 3 g/dL and a white blood cell count of $1300/\text{mm}^3$. He had a serum zinc concentration of 280 $\mu\text{g/mL}$ and low serum copper concentration of $<0.05 \mu\text{g/mL}$.⁵⁷ The patient refused surgery to remove the coins, which formed a massive bezoar in his GI tract. The patient continued to ingest coins and ultimately died of sepsis and multiorgan failure. An autopsy revealed a coin mass weighing 1870 g in his stomach and another bezoar at the site of a sigmoid volvulus.

Over a 6 to 7 month period, a 17 year-old boy used significant doses of oral vitamins and mineral supplements containing zinc to treat acne and developed copper deficiency and anemia, leukopenia, and neutropenia.⁸⁷ A 28 month-old boy developed anemia, neutropenia, and developmental delay after 11 months of parental administration of 314 mg/d of oral zinc gluconate (3.6 mg/kg/d of elemental zinc).⁹⁶ Hyperzincemia and hypocupremia were present and improved after discontinuation of zinc without copper supplementation.

It is suggested that zinc and other transition metals may be important in the pathogenesis of demyelinating diseases.^{59,81} Clusters of cases of multiple sclerosis (MS) were described in northern New York in a factory where zinc was the primary occupational exposure. One hypothesis is that the allele frequency for transferrin (an iron-and zinc-binding protein) may differ in these MS subjects.^{89,95} Another cluster was found in Canada where excess metals, including zinc, were found in the soil and water.^{39,51,52} A conclusive link to MS, however, has not been established.

Since the prostate contains the highest concentration of zinc in the human body, the role of zinc in the development of prostate cancer has been investigated. Specifically, American men participating in the Health Professionals Follow-Up Study were followed for 14 years, from 1986 to 2000. Of the 46,974 in the cohort, 2901 new cases of prostatic cancer were diagnosed, with 434 of them considered to be in an advanced stage.⁶³ Men who used zinc supplementation at a dose $>100 \text{ mg/d}$ had a relative risk of 2.29 for advanced prostate cancer, and those using zinc for longer than 10 years had a relative risk of 2.37. Neither the International Agency for Research on Cancer (IARC) nor the Environmental Protection Agency (EPA) currently classify zinc as a carcinogen.

The Third National Health and Nutrition Examination Survey examined the association of higher dietary zinc intake on the risk of kidney stone disease. Dietary zinc intake of greater than 15 mg/d was associated with a significantly increased risk of kidney stones compared to those with a dietary zinc intake less than 7 mg/d. More rigorous studies are required to determine causality and a potential underlying mechanism for this association.⁹⁷

A neurologic syndrome of progressive myeloneuropathy called “swayback” is defined by a spastic gait, usually a prominent sensory ataxia, and hematologic manifestations.^{58,59,61,62} These cases involve patients with copper deficiency and typically elevated serum zinc concentrations. A history of excess zinc exposure is obtained in some but not all patients. The potential of an inherited zinc overload syndrome has been considered.⁴¹ A 46 year-old man presented with evidence of bone marrow suppression followed by sensory ataxia and a progressive myelopathy. His neuroimaging evaluation was normal. His only remarkable laboratory studies included an elevated serum zinc concentration of 184 $\mu\text{g/dL}$ (28.2 $\mu\text{mol/L}$) and a low copper concentration of $<10 \mu\text{g/dL}$ ($<1.57 \mu\text{mol/L}$). There was no known occupational exposure or supplementation of zinc by history. Although his copper deficit improved with copper therapy, hyperzincemia persisted for more than the 3 years that he was followed. More recently, an unusual source of high zinc concentrations was related to denture creams, which may contain as much as 34 g of zinc per gram of cream. Four patients with chronic exposure to excess denture cream developed neurological abnormalities in the setting of hyperzincemia with associated hypocupremia.⁷³ Multiple other reports have confirmed the relationship between denture cream, hyperzincemia, hypocupremia, and the development of this progressive myeloneuropathy. The history in these patients often reveals poor fitting dentures as well as use of dentures during sleep.^{3,11,42,94}

Patients with underlying Wilson disease are also at risk for chronic zinc overload syndromes due to treatment. Recent reports have raised increased concerns for the use of zinc in the treatment of Wilson disease with recommendations for more frequent monitoring of zinc and copper blood concentrations.^{49,84,106}

Chronic inhalation of zinc oxide can lower blood copper and serum calcium concentrations. However, no long term effect on ventilatory function or chest radiography is reported.²⁹

Occupational Exposures

Since 1983, the US penny is composed of 97.5% zinc and 2.5% copper.¹⁰¹ Zinc is widely used in industry because it enhances the durability of iron and steel alloys; it also is commonly used in construction. Galvanization involves coating an iron product with metallic zinc to prevent it from oxidizing (rusting). Electroplaters, smelters, jewelers, artists working on stained glass or sculpting metal, as well as aircraft manufacturing workers, are routinely exposed to zinc. Zinc chloride is an essential component of flux, which can be used for soldering of galvanized iron.

Zinc is present in drinking water and beverages stored in metal containers or that flow through pipes coated with zinc. Zinc concentrations in air are typically low; average zinc concentrations in the United States are $<1 \mu\text{g}/\text{m}^3$. Air concentrations near industrial zones can be higher, and may be substantially greater in certain occupational settings. The currently accepted occupational threshold limit value (TLV)-time-weighted average (TWA) is $1 \text{ mg zinc}/\text{m}^3$.⁸⁵

Metal Fume Fever

Metal fume fever typically occurs within 12 hours after an exposure to metal oxide fumes. Patients can develop fever, chills, cough, myalgias, muscle cramping, chest pain, dyspnea, dry throat, and a metallic taste in the mouth. Although exposure to zinc oxide fumes is the commonest zinc etiology, other zinc compounds may be implicated. The chest radiograph is often normal, but may show an infiltrate. Hypoxia and tachycardia are rare, but may occur. Overall, however, the syndrome is relatively benign, with tolerance developing within days.²⁹ An immune mechanism is suggested, and chronic exposure may lead to sensitization (Chap. 124).²³

DIAGNOSTIC TESTING

Because zinc is ubiquitous in the environment and laboratory, great care must be taken to avoid contamination of any samples intended for investigation.⁸⁵ Because elevated zinc concentrations cause copper deficiency, a serum copper and ceruloplasmin concentration should be obtained in patients with suspected zinc poisoning.

Urine zinc concentrations are not well defined. In a cohort of non-occupationally exposed patients, the mean urine concentrations were $450 \mu\text{g}/\text{L}$, with a maximum concentration up to $1300 \mu\text{g}/\text{L}$.⁷² In the United States, normal urine values are generally accepted as $<500 \mu\text{g}/\text{d}$. The National Institute for Occupational Safety and Health established detection limits in urine and blood or tissue as low as $0.1 \mu\text{g}$ per sample and $1 \mu\text{g}/100 \text{ g}$, respectively. Testing requires extraction of the metals from urine with polydithiocarbamate resin prior to digestion with concentrated acids and analysis.⁸⁵

Errors can be caused by incorrect sample collection, equipment malfunction or miscalibration, inadequate reagent purity, and atmospheric deposition. Zinc oxide powder in some gloves can contaminate specimens, as can the rubber stoppers in certain blood collection tubes. Specific tubes are recommended with negligibly low concentrations of trace elements.¹⁹ During sample analysis, laminar flow is recommended to prevent airborne particles from interfering.

Abdominal radiographs may play a role in determining the gastrointestinal burden of zinc, especially following ingestions of pennies. This may guide the decision to continue gastrointestinal decontamination in certain circumstances.¹⁶ (See Management below.)

Neuroimaging in patients with chronic zinc exposure and secondary copper deficiency may reveal characteristic findings. The MRI typically reveals increased T2 signal in the dorsal columns of the cervical spinal cord similar to that found in B_{12} deficiency.⁶⁰ These lesions are thought to represent Wallerian degeneration and demyelination of white matter. One case showed evidence of bilateral subcortical hyperintense T2 abnormalities on an MRI of the brain.⁷³ These findings are the result of copper deficiency and not necessarily zinc toxicity.

MANAGEMENT

Treatment for acute oral zinc (Zn^{2+}) toxicity is primarily supportive. Efforts should focus on hydration and antiemetic therapy. H_2 receptor antagonists or proton pump inhibitors may relieve abdominal discomfort when given for several days following the zinc salt ingestion.⁹

Gastrointestinal decontamination after zinc salt ingestion may include whole-bowel irrigation (WBI). A radiograph in a 16 year-old boy who ingested 50 (500 mg) zinc sulfate tablets noted no change in tablet position 4 hours after gastric emptying with induced emesis followed by orogastric lavage. Within one hour of institution of WBI therapy, zinc tablets were present in the rectal effluent.¹⁶ Zinc containing penny ingestion may provide a unique challenge. A schizophrenic patient required laparotomy and gastrotomy to remove a total of 275 coins.⁷⁶

The data regarding the efficacy of chelation therapy for zinc is limited in humans. Edetate calcium disodium

(CaNa₂EDTA) was used successfully in several cases, including a child⁷⁹ and a 24 year-old man who were exposed to zinc chloride as a component of soldering flux.²² The combination of CaNa₂EDTA and BAL (British anti-Lewisite) was used successfully in a 16 month-old 74 hours after ingestion.⁷¹

Both DTPA (diethylenetriaminepentaacetic acid) and EDTA (ethylenediaminetetraacetic acid) were effective in enhancing the urinary excretion of zinc in a rodent model of zinc acetate poisoning.²⁷ DTPA had its greatest antidotal efficacy when given within 30 minutes of the intraperitoneal injection of zinc acetate.⁶⁵ The urinary excretion of zinc increased 1.6-to 44-fold following a 3 mg/kg intravenous dose of DMPS (sodium 2,3-dimercaptopropane-1-sulfonate) in one human study where metal toxicity in patients with dental amalgams was the focus.⁹⁹ Two potential zinc-selective chelators, DPESA (4- {[2-(bis-pyridin-2-ylmethylamino) ethylamino]-methyl} phenylmethanesulfonic acid) sodium salt, as well as TPESA (4- {[2-bis-pyridin-2-ylmethylamino)ethyl]pyridine-2-ylmethylamino}-methyl)phenyl]methanesulfonic acid) sodium salt, rapidly chelate zinc in vitro, but further detailed in vivo studies are needed before their clinical use can be considered.⁵⁵ Finally, an iron chelator, deferiprone, was incidentally noted to cause decreased serum zinc concentrations when it was used to lower iron concentrations in patients with transfusion overload (Antidotes in Depth: A7).¹⁰³ A subsequent prospective trial showed enhanced urinary excretion of zinc in children with thalassemia major who had received multiple blood transfusions.¹⁰

Many of the clinical manifestations and metabolic effects of zinc toxicity are due to its ability to cause copper deficiency. In patients with zinc overload related copper deficiency, the supplementation of oral copper alone improved the hematopoietic effects and prevent further neurological deterioration without chelation therapy.⁸⁶

Though treatment with copper sulfate alone may be adequate for patients with neurological sequelae and mild hematopoietic effects, chelation may be required for patients with hemodynamic compromise or other consequential systemic manifestations. Limited experience exists with regard to treatment of these patients; however, 1000 mg/m²/d IV CaNa₂EDTA divided every 6 hours seems to be a reasonable choice based on case reports of successful use. The potential of BAL to increase copper elimination should limit its clinical use.

Intravenous N-acetylcysteine (NAC) increased the urinary zinc excretion in a patient who had inhaled zinc chloride fumes.⁷⁸ Two individuals with inhalational zinc chloride induced ARDS had simultaneous transient decreases in serum zinc concentrations and increases in urinary zinc excretion when treated with intravenous and nebulized NAC.⁴⁷ However, these individuals succumbed at days 25 and 32 after inhalation. Although an increase in urinary zinc excretion was noted in one rat model, 10 healthy volunteers who were treated with oral NAC for 2 weeks had no significant change in either their serum or urine zinc concentrations.⁴⁶ This therapy requires further study and cannot be recommended at this time.

Supportive care is used for patients with inhalational zinc exposures, including oxygen therapy and bronchodilators as clinically indicated, but these patients may necessitate ventilatory support in severe cases. Exposure to zinc oxide fumes by rescuers is minimal, although respiratory protective equipment should be worn.⁹⁰ In a case series of five soldiers exposed to zinc chloride smoke bombs during military training, the two individuals not wearing gas masks developed ARDS;⁴⁷ the others remained clinically well. A 23 year-old man developed severe ARDS after inhalation of zinc chloride from a smoke bomb during a military drill. After extensive ventilatory supportive efforts, tube thoracostomy, intravenous antibiotics, and intravenous corticosteroids, the patient continued to deteriorate. The patient was placed on extracorporeal life support (ECLS), weaned off the ventilator by day 30, and survived. If ECLS is available, it may be beneficial. More prospective studies are required to determine the extent of the benefit of ECMO.²¹

Metal fume fever is typically self limited. Nonsteroidal antiinflammatory drugs should be sufficient to relieve the transient discomfort. Personal protective equipment and or adequate engineering design and strategies may allow the individual to continue to work in the particular occupational site.

Dermal decontamination is paramount to prevent direct epidermal effects or systemic absorption of zinc salts.¹⁵ However, water should not be used to perform dermal decontamination of patients exposed to metallic zinc because zinc metal may ignite when wet. Treatment in these situations includes mechanical removal of any metallic particles with forceps and the application of mineral oil to the affected skin to protect the metal from ambient moisture.

SUMMARY

- Zinc exposures in humans occur as part of the diet, medicinal uses, nutritional supplements, and in occupational settings.
- The clinical manifestations of zinc toxicity include acute, life-threatening gastrointestinal and pulmonary effects, which are generally treated with supportive care.
- Chronic zinc toxicity manifests primarily as copper deficiency.
- Copper supplementation alone often corrects systemic manifestations.
- Chelation therapy may be considered in acutely life threatening circumstances.

J. HOUSEHOLD PRODUCTS

CASE STUDY 8

History A 38 year-old woman was brought to the hospital directly from the airport because she complained of shortness of breath immediately after exiting the airplane. She had a history of depression and took amitriptyline and zolpidem and admitted to daily alcohol use. She also had a history of hypertension but did not recall the name of her medication. She reported that she was well prior to getting on the flight and only drank two beers about 6 hours apart. During the flight, she noted some abdominal and back pain, followed by difficulty breathing. She denied ingestions or suicidal ideations.

Physical Examination On arrival to the hospital she was noted to be severely short of breath with the following vital signs: blood pressure, 156/92 mm Hg; pulse, 140 beats/min; respiratory rate, 42 breaths/min; temperature, 98.2°F (36.8°C); oxygen saturation, 100% on a 100% non-rebreather mask. Her head was without signs of trauma, and her pupils were equally round and sluggishly reactive to light. Her neck was supple and her chest was clear. Her heart was tachycardic but regular, and without murmurs, rubs, thrills, or gallops. Her abdomen was soft with normal bowel sounds and no organomegally. She was slightly tender in all four quadrants, but without guarding or rebound. Her extremities were without clubbing, cyanosis, or edema, and a brief neurological examination was without deficit or focality.

Immediate Management The patient was immediately intubated, sedated with midazolam, and attached to a mechanical ventilator. A rapid bedside glucose was reported as 50 mg/dL, and she was given 25 g of D₅₀W and 100 mg of thiamine intravenously. An arterial blood gas revealed a pH of 6.80, a PCO₂ of 24 mm Hg, and a PO₂ of 106 mm Hg on room air. A CT scan of the chest was negative for pulmonary embolus. Standard laboratories are shown in [Table CS8–1](#).

Table CS8–1. Laboratory Analyses

Sodium mEq/L	Potassium mEq/L	Chloride mEq/L	Bicarbonate mEq/L	BUN mg/dL	Creatinine mg/dL	Glucose* mg/dL	Calcium mg/dL
149	3.4	104	5	14	1.4	124	8.9

* = These studies were obtained after D₅₀W was given.

What Is the Differential Diagnosis? The laboratory analysis shows a severe metabolic acidosis with elevated anion gap (40 mEq/L). Of the many mnemonics used to help recall the differential diagnosis, one of the most popular is MUDPILES (Methanol; Uremia; Diabetic and other ketoacidoses; Phenformin and metformin; Iron and isoniazid; Lactate; Ethylene glycol; Salicylates) (Chap. 19). It should be remembered that this is an imperfect mnemonic in that it is easy to forget cyanide, theophylline, and a number of other xenobiotics that are not directly noted.

What Clinical and Laboratory Analyses Can Help Identify the Etiology? A rapid clinical assessment will help to narrow the differential diagnosis. For example, iron poisoning is almost always associated with vomiting ([Chap. 46](#)), and isoniazid rapidly produces seizures ([Chap. 58](#)). Uremia can be excluded based on the BUN and creatinine. Likewise, the presentation glucose concentration helps diminish the probability of diabetic ketoacidosis.

At this point, additional rapid tests are useful. A urinalysis showing ketones would be helpful in cases of alcoholic ketoacidosis ([Chap. 80](#)) or salicylates ([Chap. 39](#)) and might show oxalate crystals or fluorescence following ethylene glycol poisoning ([Chap. 109](#)). A lactate concentration would be elevated in patients with metformin toxicity ([Chap. 53](#)) and might be falsely elevated from glycolate accumulation following ethylene glycol poisoning ([Chap. 109](#)). Additionally, most laboratories can determine salicylate concentrations rapidly. An ethanol concentration is exceedingly helpful in that it might be low in those with alcoholic ketoacidosis and if elevated essentially excludes methanol or ethylene glycol poisoning because it would be protective. Finally, if ethanol and methanol concentrations are not available, an osmol gap can be calculated, although caution is advised when interpreting the results ([Chap. 19](#)).

Further Diagnosis and Treatment Additional studies revealed the following: urine was negative for ketones and crystals; a serum lactate was 6 mmol/L; ethanol and salicylate concentrations were negative. Despite receiving fluids, thiamine, and glucose (empiric treatment for alcoholic ketoacidosis), the patient's metabolic acidosis persisted. Because of the severity of the anion gap acidosis and the lack of alternative diagnoses, a loading dose of fomepizole was administered (Antidotes in Depth: A30) for presumed toxic alcohol (methanol or ethylene glycol) ingestion. Intravenous hypertonic sodium bicarbonate was infused for presumed methanol poisoning (Antidotes in Depth: A5) as a repeat creatinine concentration was slightly improved prior to fomepizole administration making ethylene glycol

poisoning less likely ([Chap. 109](#)).

Nephrology was consulted for hemodialysis, and two 4 hour hemodialysis treatments were performed 8 hours apart. A second dose of fomepizole was given in between the hemodialysis treatments. After the second treatment, her anion gap was 8 mEq/L, and sedation was weaned. The patient was extubated easily a few hours later, and her mental status and neurologic examination were normal. The next day her presentation methanol concentration was reported from the reference laboratory as 45 mg/dL. A formal ophthalmology evaluation was unremarkable, and the patient was transferred to psychiatry.

104 ANTISEPTICS, DISINFECTANTS, AND STERILANTS

Paul M. Wax

INTRODUCTION

Joseph Lister, often considered the father of modern surgery, revolutionized surgical treatment and dramatically reduced surgical mortality by introducing the concept of antisepsis to the surgical theatre.⁴⁸ It was Lister’s understanding that microorganisms contributed to infection and sepsis from even the most trivial wounds that led to his search for chemicals that would prevent such infection. Lister demonstrated that phenol (carbolic acid), a chemical that was used to treat foul-smelling sewage, could be used to clean out dirty wounds of patients with compound fractures and dramatically increase survival rates. Soon thereafter, the use of phenol was expanded to surgical instrument cleaning and as a surgical hand scrub wash, ushering in the modern surgical era.

Antiseptics, disinfectants, and sterilants are a diverse group of germicides used to prevent the transmission of microorganisms to patients (Table 104–1). Although these terms are sometimes used interchangeably and some of these xenobiotics are used for both antisepsis and disinfection, the distinguishing characteristics between the groups are important to emphasize. An antiseptic is a chemical that is applied to living tissue to kill or inhibit microorganisms. Iodophors, chlorhexidine, and the alcohols (ethanol and isopropanol) are commonly used antiseptics. A disinfectant is a chemical that is applied to inanimate objects to kill microorganisms. Bleach (sodium hypochlorite), phenolic compounds, formaldehyde, hydrogen peroxide liquid, ortho-phthalaldehyde, and quaternary ammonium compounds are examples of currently used disinfectants. Neither antiseptics nor disinfectants have complete sporicidal activity. A sterilant is a chemical that is applied to inanimate objects to kill all microorganisms as well as spores. Ethylene oxide, glutaraldehyde, hydrogen peroxide gas, and peracetic acid are examples of sterilants. Not unexpectedly many of the xenobiotics used to kill microorganisms also demonstrate considerable human toxicity.^{5,18,68}

TABLE 104–1. Antiseptics, Disinfectants, Sterilants, and Related Xenobiotics

<i>Xenobiotic</i>	<i>Commercial Product</i>	<i>Use</i>	<i>Toxic Effects</i>	<i>Therapeutics and Evaluation</i>
Acids				
Boric acid	Borax Sodium perborate Dobell solution	Antiseptic Mouthwash Eyewash Roach powder	Blue-green emesis and diarrhea Boiled lobster appearance of skin CNS depression; kidney failure	GI decontamination Hemodialysis (rare)
Alcohols (Chaps. 80 and 109)				
Ethanol	Rubbing alcohol (70% ethanol)	Antiseptic Disinfectant	CNS depression Respiratory depression Dermal irritant	Supportive
Isopropanol	Rubbing alcohol (70% isopropanol)	Antiseptic Disinfectant	CNS depression Respiratory depression Ketonemia, ketonuria GI irritation/bleeding Hemorrhagic tracheobronchitis	Supportive Hemodialysis (rare)
Aldehydes				
Formaldehyde	Formalin (37% formaldehyde, 12%–15% methanol)	Disinfectant Fixative Urea insulation	Caustic CNS depression Carcinogen	Gastric lavage Hemodialysis Sodium bicarbonate Endoscopy Folinic acid Supportive
Glutaraldehyde	Cidex (2% glutaraldehyde)	Sterilant	Mucosal and dermal irritant	Supportive
Chlorinated Compounds				
Chlorhexidine	Hibiclens	Antiseptic	GI irritation	Supportive
Chlorates	Sodium chlorate Potassium chlorate	Antiseptic Matches Herbicide	Hemolytic anemia Methemoglobinemia Kidney failure	Exchange transfusion Hemodialysis
Chlorine		Disinfectant	Irritant	Supportive
Chlorophors (sodium hypochlorite)	Household bleach (5% NaOCl) Dakin solution (1 part 5% NaOCl, 10 parts H ₂ O)	Disinfectant Decontaminating solution	Mild GI irritation	Endoscopy (rare)
Ethylene Oxide		Sterilant Plasticizer	Irritant CNS depression Peripheral neuropathy Carcinogen?	Supportive
Mercurials (Chaps. 55 and 98)				
	Merbromin 2% (Mercurochrome)	Antiseptic (obsolete)	CNS	Gastric lavage, activated charcoal dimercaprol, succimer
	Thimerosal (Merthiolate)		Renal	
Iodinated Compounds				
Iodine	Tincture of iodine (2% iodine, 2% sodium iodide, and 50% ethanol) Lugol solution (5% iodine)	Antiseptic	Caustic	Milk, starch, sodium thiosulfate Endoscopy
Iodophors	Povidone-iodine (Betadine) (0.01% iodine)	Antiseptic	Limited	Same as iodine
Oxidants				
Hydrogen peroxide	H ₂ O ₂ , 3%—household H ₂ O ₂ , 30%—industrial	Disinfectant	Oxygen emboli GI caustic	Gastric lavage Radiographic evaluation Endoscopy
Potassium permanganate	Crystals, solution	Antiseptic	Oxidizer, caustic; increased serum manganese	Decontamination Endoscopy as needed

Phenols				
Nonsubstituted	Phenol (carbolic acid)	Disinfectant	Caustic Dermal burns Cutaneous absorption CNS effects	Decontamination: polyethylene glycol or water Endoscopy as needed
Substituted	Hexachlorophene	Disinfectant	CNS effects	Supportive
Quaternary Ammonium Compounds				
Benzalkonium chloride	Zephiran	Disinfectant	GI caustic	Consider endoscopy

The choice of disinfectant or sterilant depends on the degree of risk for infection involved in use of medical and surgical instruments and patient care items. Surgical instruments and cardiac and urinary catheters that enter the vascular system or other sterile tissues (so called critical items) must be cleaned with a sterilant while instruments that contact mucous membranes or nonintact skin such as GI endoscopes and laryngoscope blades (semicritical items) can be cleaned with a high level disinfectant (ortho-phthalaldehyde, 7.5% hydrogen peroxide). Noncritical items such as bedpans, blood pressure cuffs, crutches, and computers are those that come in contact with intact skin but not mucous membranes and can be cleaned with intermediate level and low level disinfectants (bleach or phenol). Whether a chemical is classified as a sterilant or disinfectant may depend on how it is used. Device sterilization with glutaraldehyde 3% requires a 10-hour cleaning cycle while high-level disinfection using the same chemical requires a 25 minute cleaning cycle.

The use of these xenobiotics evolved during the 20th century as their toxicity and the principles of microbiology became better understood. Two of the more toxic antiseptics—iodine and phenol—were gradually replaced by the less toxic iodophors and substituted phenols. The use of mercuric chloride was superseded by the organic mercurials (eg, merbromin, thimerosal), which also proved toxic. In recent years, newer xenobiotics, such as quaternary ammonium compounds, ethylene oxide, glutaraldehyde, and a peracetic acid-hydrogen peroxide mixture, are more extensively used.

ANTISEPTICS

Chlorhexidine

This cationic biguanide has been in use as an antiseptic since the early 1950s. It is found in a variety of skin cleansers, usually as a 4% emulsion (Hibiclens), and may also be found in mouthwash. Chlorhexidine is reported to have low toxicity.

Clinical Effects. Few cases of deliberate ingestion of chlorhexidine are reported. Symptoms are usually mild, and gastrointestinal irritation is the most likely effect after ingestion.²⁶ Chlorhexidine has poor enteral absorption. In one case, ingestion of 150 mL of a 20% chlorhexidine gluconate solution resulted in oral cavity edema and significant irritant injury of the esophagus.¹²³ In the same case, liver enzymes concentrations rose to 30 times normal on the fifth day after ingestion. Liver biopsy showed lobular necrosis and fatty degeneration. In another case, the ingestion of 30 mL of a 4% solution by an 89 year-old woman did not result in any GI injury.⁵⁰ An 80 year-old woman with dementia ingested 200 mL of a 5% chlorhexidine solution and subsequently aspirated.⁷⁸ She rapidly developed hypotension, respiratory distress, coma, and died 12 hours following ingestion.

Intravenous administration of chlorhexidine is associated with acute respiratory distress syndrome (ARDS),⁸⁷ and hemolysis, although the latter may be caused by the hypotonicity of the injected solution.²⁷ Inhalation of vaporized chlorhexidine causes methemoglobinemia, likely as a consequence of the conversion of chlorhexidine to p-chloraniline.¹⁹⁹ In one patient, the rectal administration of 4% chlorhexidine resulted in acute colitis with ulcerations.⁶⁷

Topical absorption of chlorhexidine is negligible. Contact dermatitis is reported in up to 8% of patients who received repetitive topical applications of chlorhexidine.⁶⁸ More ominously, anaphylactic reactions, including shock, are associated with dermal application.^{7,141} Some of these cases of chlorhexidine-related anaphylaxis occurred during surgery, appearing 15 to 45 minutes after application of the antiseptic.¹³ Eye exposure may result in corneal damage.¹⁹³

Management. Treatment guidelines for chlorhexidine exposure are similar to those for other potential caustics (Chap. 106). Patients with significant symptoms may require endoscopy, but the need for such extensive evaluation is quite uncommon.

Hydrogen Peroxide

Hydrogen peroxide, an oxidizer with weak antiseptic properties, has been used for many years as an antiseptic and a disinfectant.²⁰² This oxidizer is generally available in two strengths: dilute, with a concentration of 3% to 9% by weight (usually 3%), sold for home use, and concentrated, with a concentration greater than 10%, used primarily for industrial purposes. Commercial strength hydrogen peroxide is commonly found in solutions varying from 27.5% to 70%. Home uses

for dilute hydrogen peroxide include cerumen removal, mouth gargle, vaginal douche, enema, and hair bleaching. Dilute hydrogen peroxide is also sometimes used as a veterinary emetic. Commercial uses of the more concentrated solutions include bleaching and cleansing textiles and wool, and producing foam rubber and rocket fuel. A 35% hydrogen peroxide solution is also available to the general public in health food stores and is sold as “hyperoxygenation therapy” and as a health food additive to aerate health food drinks.⁸⁴ This potentially dangerous therapy is touted as a treatment for a variety of conditions, including AIDS and cancer.

Toxicity from hydrogen peroxide may occur after ingestion, inhalation, injection, wound irrigation, rectal administration, dermal exposure and ocular exposure.²⁰² Hydrogen peroxide has two main mechanisms of toxicity: local tissue injury and gas formation. The extent of local tissue injury and amount of gas formation are determined by the concentration of the hydrogen peroxide. Dilute hydrogen peroxide is an irritant, and concentrated hydrogen peroxide is a caustic. Gas formation results when hydrogen peroxide interacts with tissue catalase, liberating molecular oxygen, and water. At standard temperature and pressure, 1 mL of 3% hydrogen peroxide liberates 10 mL of oxygen, whereas 1 mL of the more concentrated 35% hydrogen peroxide liberates more than 100 mL of oxygen. Gas formation can result in life-threatening embolization. The ingestion of two sips of 33% hydrogen peroxide resulted in cerebral gas embolization and hemiplegia.¹⁶⁴ Gas embolization may be a result of dissection of gas under pressure into the tissues or of liberation of gas in the tissue or blood following absorption. The use of hydrogen peroxide in partially closed spaces, such as operative wounds, or its use under pressure during wound irrigation increases the likelihood of embolization.

Clinical Effects. Airway compromise manifested by stridor, drooling, apnea, and radiographic evidence of subepiglottic narrowing may occur.⁴³ The combination of local tissue injury and gas formation from the ingestion of concentrated hydrogen peroxide may cause abdominal bloating, abdominal pain, vomiting, and hematemesis.^{53,116} Endoscopy may show esophageal edema and erythema and significant gastric mucosal erosions.^{154,171}

Symptoms consistent with sudden oxygen embolization include rapid deterioration in mental status, cyanosis, respiratory failure, seizures, ischemic ECG changes, and acute paraplegia.^{55,112} A 2 year-old boy died after ingesting 120 to 180 mL of 35% hydrogen peroxide.²⁹ Antemortem chest radiography showed gas in the right ventricle, mediastinum, and portal venous system. Portal vein gas is also a prominent feature in other cases.^{53,84,147} Arterialization of oxygen gas embolization may result in cerebral infarction.¹⁷⁷ Encephalopathy with cortical visual impairment²³ and bilateral hemispheric infarctions detected by MRI imaging may occur after ingestion of concentrated hydrogen peroxide.⁸⁶ In a case of acute paraplegia after the ingestion of 50% hydrogen peroxide, MRI revealed discrete segmental embolic infarctions of the cervical and thoracic spinal cord as well as both cerebral hemispheres and left cerebellar hemisphere.¹¹²

Death from intravenous injection of 35% hydrogen peroxide is also reported.¹⁰⁵ The use of a concentrated hydrogen peroxide solution as part of a hair highlighting procedure resulted in a severe scalp injury including necrosis of the galea aponeurotica.¹⁷²

Clinical sequelae from the ingestion of dilute hydrogen peroxide are usually much more benign.^{43,75} Nausea and vomiting are the most common symptoms.⁴³ A whitish discoloration may be noted in the oral cavity. Gastrointestinal injury is usually limited to superficial mucosal irritation, but multiple gastric and duodenal ulcers, accompanied by hematemesis, and diffuse hemorrhagic gastritis are reported.^{75,129} Portal venous gas embolization may occur as a result of the ingestion of 3% hydrogen peroxide.^{30,129,158}

The use of 3% hydrogen peroxide for wound irrigation may result in significant complications. Extensive subcutaneous emphysema occurred after a dog bite to a human's face was irrigated under pressure with 60 mL of 3% hydrogen peroxide.¹⁶² Systemic oxygen embolism, causing hypotension, cardiac ischemia, and coma, resulted from the intraoperative irrigation of an infected herniorrhaphy wound.¹² Gas embolism, resulting in intestinal gangrene, was reported to occur following colonic lavage with 1% hydrogen peroxide during surgical treatment of meconium ileus.¹⁷⁵ Multiple cases of acute colitis are reported as a complication of administering 3% hydrogen peroxide enemas.¹²⁵ The use of 3% hydrogen peroxide as a mouth rinse is associated with the development of oral ulcerations.¹⁶¹ Ophthalmic exposures may result in conjunctival injection, burning pain, and blurry vision.^{43,124} Optic neuropathy including transient blindness (ability to visualize shadows only) and subsequent optic atrophy from possible inhalational of hydrogen peroxide is described.⁴⁴ Cough, wheezing, and shortness of breath is associated with occupational exposure to peracetic acid-hydrogen peroxide mixtures used to clean endoscopic equipment.³⁵

Diagnosis. A careful examination should be performed to detect any evidence of gas formation. A chest radiograph might reveal gas in the cardiac chambers, mediastinum, or pleural space. An abdominal radiograph might show gas in the GI tract or portal system and define the extent of bowel distension. MRI and CT scan might be useful for detecting brain and spinal cord lesions secondary to gas embolism.^{6,86,112} Endoscopic evaluation can help determine the extent of mucosal injury.¹⁵⁴

Management. The treatment of patients with hydrogen peroxide ingestions depends, to a large degree, on whether the patient has ingested a diluted or concentrated solution. Those with ingestions of concentrated solutions require expeditious

evaluation. Dilution with milk or water, although unstudied, is unlikely to be helpful. Nasogastric aspiration of hydrogen peroxide might be helpful if the patient presents immediately after ingestion. Induced emesis is contraindicated and activated charcoal offers no antidotal benefit. Patients with abdominal distension from gas formation should be treated with nasogastric suctioning. Those with clinical or radiographic evidence of gas in the heart should be placed in the Trendelenburg position to prevent gas from blocking the right ventricular outflow tract. Careful aspiration of intracardiac air through a central venous line may be attempted in patients in extremis.²⁹ Case reports suggest that hyperbaric therapy may be useful in cases of life-threatening gas embolization after hydrogen peroxide ingestion.^{53,84,112,131,147,199} Asymptomatic patients who unintentionally ingest small amounts of 3% hydrogen peroxide can be safely observed at home.

Iodine and Iodophors

Iodine is one of the oldest topical antiseptics.¹⁷³ Iodine usually refers to molecular iodine, also known as I₂, free iodine, and elemental iodine, which is the active ingredient of iodine-based antiseptics. The use of ethanol as the solvent, such as tincture of iodine, allows substantially more concentrated forms of I₂ to be available. I₂ and tincture of iodine ingestions are much less common than in the past as a result of the change in antiseptic use from iodine to iodophor antiseptics.⁴⁵

Iodophors have molecular iodine compounded to a high-molecular-weight carrier or to a solubilizing agent. Povidone-iodine (Betadine), a commonly used iodophor, consists of iodine linked to polyvinylpyrrolidone (povidone). Iodophors, which limit the release of molecular iodine and are generally less toxic, are the current standard iodine-based antiseptic preparations. Iodophor preparations are formulated as solutions, ointments, foams, surgical scrubs, wound-packing gauze, and vaginal preparations. The most common preparation is a 10% povidone-iodine solution that contains 1% “available” iodine (referring to all oxidizing iodine species), but only 0.001% free iodine (referring only to molecular iodine).^{18,68}

Iodine is used to disinfect medical equipment and drinking water. Iodine is effective against bacteria, viruses, protozoa, and fungi, and is used both prophylactically and therapeutically.³⁶ Iodine is cytotoxic and an oxidant. It is thought to work by binding amino and heterocyclic nitrogen groups, oxidizing sulfhydryl groups, and saturating double bonds. Iodine also iodinates tyrosine groups.⁶⁸

There may be significant systemic absorption of iodine from topical iodine or iodophor preparations.¹⁴⁹ Markedly elevated iodine concentrations occur in patients who receive topical iodophor treatments to areas of dermal breakdown, such as burn injuries.¹⁰² Significant absorption occurs when iodophors are applied to the vagina, perianal fistulas, umbilical cords, and the skin of low-birth-weight neonates.¹⁸⁴ The mucosal application of povidone-iodine during a hysteroscopy procedure resulted in acute kidney injury (AKI) that transiently required hemodialysis.¹⁷ A fatality following intraoperative irrigation of a hip wound with povidone-iodine is also reported.³⁷ In this latter case, the postmortem serum iodine concentration was 7000 µg/dL (normal: 5–8 µg/dL).

Clinical Effects. Problems associated with the use of iodine include unpleasant odor, skin irritation, allergic reactions, and clothes staining. Ingestion of iodine may cause abdominal pain, vomiting, diarrhea, GI bleeding, delirium, hypovolemia, anuria, and circulatory collapse. Severe caustic injury of the GI tract may occur. The ingestion of approximately 45 mL of a 10% iodine solution resulted in death from multisystem failure 67 hours after ingestion.⁴⁶ In another case, the ingestion of 200 mL of tincture of iodine containing 60 mg/mL iodine and 40 mg/mL potassium iodide in 70% v/v ethanol resulted in AKI and severe hemolysis.¹¹⁹

Reports of adverse consequences from iodophor ingestions are rare. In one case report, a 9 week-old infant died within 3 hours of receiving povidone-iodine by mouth.¹⁰⁰ In this unusual case, the child was administered 15 mL of povidone-iodine mixed with 135 mL of polyethylene glycol by nasogastric tube over a 3-hour period for the treatment of infantile colic. Postmortem examination showed an ulcerated and necrotic intestinal tract. A blood iodine concentration of 14,600 µg/dL was recorded. Significant toxicity from intentional ingestions of iodophors in adults is not documented.

Acid–base disturbances are among the most significant abnormalities associated with iodine and iodophors. Metabolic acidosis occurred in several burn patients after receiving multiple applications of povidone-iodine ointment.^{102,150} These patients had elevated serum iodine concentrations and normal lactate concentrations. The exact etiology of the acidosis remains unclear. Postulated mechanisms for the acidosis include the povidone-iodine itself (pH 2.43), bicarbonate consumption from the conversions of I₂ to NaI, and decreased renal elimination of H⁺ as a consequence of iodine toxicity.¹⁵⁰ Metabolic acidosis associated with a high lactate concentration after iodine ingestion likely reflects tissue destruction.³⁶

Electrolyte abnormalities also may occur following the absorption of iodine. A patient with decubitus ulcers who received prolonged wound care with povidone-iodine-soaked gauze developed hypernatremia, hyperchloremia, metabolic acidosis, and AKI.³⁷ The hyperchloremia was thought to be caused by a spurious elevation of measured chloride ions as a consequence of iodine’s interference with the chloride assay. This interference occurs on the Technicon STAT/ION autoanalyzer, but does not occur when the silver halide precipitation assay is used.³⁶ Spurious hyperchloremia from iodine (or iodide) may result in the calculation of a low or negative anion gap (Chap. 19).^{24,52}

Other problems associated with topical absorption of iodine-containing preparations are hypothyroidism (particularly in neonates),^{24,180} hyperthyroidism,^{160,165} elevated liver enzyme concentrations, neutropenia anaphylaxis,¹ and hypoxemia.³⁶ Because of the lack of consistency between iodine concentrations and symptomatology, and because many of these patients had significant secondary medical problems that may have accounted for their symptoms, the exact relationship between iodine absorption and the development of a specific clinical syndrome remains speculative. However, a clinical controlled trial that compared preterm infants exposed to either topical iodinated antiseptics or to chlorhexidine-containing antiseptics showed that the infants exposed to topical iodine-containing antiseptics were more likely to have higher TSH concentrations and elevated urine iodine concentrations than was the chlorhexidine group.¹⁰⁹

Contact dermatitis can result from repetitive applications of iodophors.¹²⁰ A dermal burn may result from the trapping of an iodophor solution under the body of a patient in a pooled dependent position or under a tourniquet.^{111,135}

Management. The patient who ingests iodine (I_2) requires expeditious evaluation, stabilization, and decontamination. Careful nasogastric aspiration and lavage may be performed to limit the caustic effect of the iodine if signs of perforation are absent. Irrigation with a starch solution will convert iodine to the much less toxic iodide and, in the process, turn the gastric effluent dark blue-purple. This change in color may serve as a useful guide in determining when lavage can be terminated. If starch is not available, milk may be a useful alternative. Instillation of 100 mL of a solution of 1% to 3% sodium thiosulfate can also be used to convert any remaining iodine to iodide. Early endoscopy may help assess the extent of the gastrointestinal injury.

Most patients with iodophor ingestion require only supportive management. The use of starch or sodium thiosulfate may be considered in symptomatic patients. Hemodialysis and continuous venovenous hemodiafiltration were used successfully to enhance elimination of iodine in a patient with CKD who had become iodine toxic and developed renal deterioration after undergoing continuous mediastinal irrigation with povidone-iodine.⁹⁵ The benefit of hemodialysis or continuous venovenous hemodiafiltration is unknown in patients with normal renal function and therefore not recommended.

Potassium Permanganate

Potassium permanganate ($KMnO_4$) is a violet water-soluble xenobiotic that is usually sold as crystals or tablets or as a 0.01% dilute solution.⁹² Historically, it was used as an abortifacient, urethral irrigant, lavage fluid for alkaloid poisoning, and snakebite remedy. Currently, potassium permanganate is most often used in baths and wet bandages as a dermal antiseptic, particularly for patients with eczema.

Potassium permanganate is a strong oxidizer, and poisoning may result in local and systemic toxicity.¹⁸² Upon contact with mucous membranes, potassium permanganate reacts with water to form manganese dioxide, potassium hydroxide, and molecular oxygen. Local tissue injury is the result of contact with the nascent oxygen, as well as the caustic effect of potassium hydroxide. A brown-black staining of the tissues occurs from the manganese dioxide. Systemic toxicity may occur from free radicals generated by absorbed permanganate ions.²⁰⁸

Clinical Effects. Following ingestion, initial symptoms include nausea and vomiting. Laryngeal edema and ulceration of the mouth, esophagus, and, to a lesser extent, the stomach, may result from the caustic effects. Airway obstruction and fatal gastrointestinal perforation and hemorrhage may occur.^{42,126,143} Esophageal strictures and pyloric stenosis are potential late complications.⁹⁸

Although potassium permanganate is not well absorbed from the GI tract, systemic absorption may occur, resulting in life-threatening toxicity. Systemic effects include hepatotoxicity, AKI, methemoglobinemia, hemolysis, hemorrhagic pancreatitis, airway obstruction, ARDS, disseminated intravascular coagulation, and cardiovascular collapse.^{107,118,126,143} Elevation in blood or serum manganese concentration may also occur, confirming systemic absorption (normal concentrations blood manganese 3.9–15.0 $\mu g/L$; serum manganese 0.9–2.9 $\mu g/L$).

Chronic ingestion of potassium permanganate may result in classic manganese poisoning (manganism) characterized by behavioral changes, hallucinations, and delayed onset of parkinsonianlike symptoms. A 66-year-old man who mistakenly ingested 10 g of potassium permanganate instead of potassium iodate over a 4-week period (because of medication mislabeling) developed impaired concentration and autonomic and visual symptoms. He also developed abdominal pain, gastric ulceration, and alopecia. Serum manganese concentration was elevated. Nine months later, the patient's neurologic examination displayed extrapyramidal signs consistent with parkinsonism (**Chap. 97**).⁸²

Management. Because the consequential effects of potassium permanganate ingestion are a result of its liberation of strong alkalis, the initial treatment of such a patient should include assessment for evidence of airway compromise. Dilution with milk or water may be useful. Patients with symptoms consistent with caustic injury should undergo early upper GI endoscopy.⁹² Corticosteroids along with antibiotics may be warranted if laryngeal edema is present. Analysis of liver enzymes, BUN, creatinine, lipase, serum manganese, and methemoglobin concentrations should be performed when systemic toxicity is suspected. Methemoglobinemia, if clinically significant, should be treated with methylene blue (**Antidotes in Depth: A42**). Dermal irrigation with dilute oxalic acid may be successful in removing cutaneous staining.¹⁸² The administration of N-acetylcysteine (**Antidotes in Depth: A3**) to increase reduced glutathione production, thereby

limiting free radical–mediated oxidative injury in cases of systemic potassium permanganate poisoning, has been suggested, but clinical trials have not been performed.²⁰⁸

OTHER ANTISEPTICS

Alcohols

Isopropanol and ethanol (Chaps. 80 and 109) are commonly used as skin antiseptics. When sold as rubbing alcohol, the standard concentration for these solutions is usually 70%. In recent years, alcohol-based hand sanitizers containing 60% to 95% ethyl or isopropyl alcohol have become ubiquitous throughout patient care units, jails, and some public buildings as a primary infection control measure. Their antiseptic action is thought to be a result of their ability to coagulate proteins.

Isopropanol is slightly more germicidal than ethanol.⁶⁸ The alcohols have limited efficacy against viruses or spores.

Isopropanol tends to be more irritating than ethanol and may cause more pronounced central nervous system depression.²⁰⁰

Unfortunately readily available alcohol-based sanitizer may be a tempting source for patients admitted with alcohol abuse disorders.^{49,204} In a recent report a patient was admitted to the hospital with chest pain. While in the hospital the patient became hypotensive and delirious. He was later found in the bathroom drinking an alcohol-based hand wash that contained 63% isopropanol.⁴⁹ The clinical effects and treatment for alcohol poisoning are discussed in Chaps. 80 and 109.

Chlorine and Chlorophors

Chlorine, one of the first antiseptics, is still used in the treatment of the community water supply and in swimming pools. Chlorine is a potent pulmonary irritant that can cause severe bronchospasm and acute lung injury. Chapter 124 contains a further discussion of chlorine.

Sodium hypochlorite (NaClO), found in household bleaches and in Dakin solution, remains a commonly used disinfectant. First used in the late 1700s to bleach clothes, its usefulness arises from its oxidizing capability, measured as “available chlorine,” and its ability to release hypochlorous acid (HClO) slowly. It is used to clean blood spills and to sterilize certain medical instruments. A 0.5% hypochlorite solution is sometimes recommended for dermal and soft-tissue wound decontamination after exposure to biologic and chemical warfare agents (Chaps. 132 and 133).⁸⁵ Toxicity from hypochlorite is mainly a result of its irritant effects. The ingestion of large amounts of household liquid bleach (5% sodium hypochlorite) on rare occasions can result in esophageal burns with subsequent stricture formation.⁵⁴ In a cat model of bleach ingestion, a high incidence of mucosal injury and stricture formation was noted.²⁰³ However, the vast majority of household bleach ingestions in humans do not cause significant GI injuries.¹⁵¹ Accordingly, endoscopic evaluation is usually not warranted when assessing most patients with household liquid bleach ingestions. The ingestion of a more concentrated “industrial strength” bleach preparation (eg, 35% sodium hypochlorite) increases the likelihood of local tissue injury and should be managed accordingly (Chap. 106).

Mercurials

Both inorganic mercurials, such as mercuric bichloride (HgCl_2), and organic mercurials, such as merbromin ($\text{C}_{20}\text{H}_8\text{Br}_2\text{HgNa}_2\text{O}_6$) (mercurochrome) and thimerosal ($\text{C}_9\text{H}_9\text{HgNaO}_2\text{S}$) (merthiolate), which both contain 49% mercury, were used in the past as topical antiseptic agents. The usefulness of mercurials is significantly limited because of their relatively weak bacteriostatic properties and the many problems associated with mercury toxicity (Chap. 98). Repeated application of topical mercurials may result in significant absorption and systemic toxicity.^{132,166} The use of high-dose hepatitis B immunoglobulin (HBIG) may cause mercury toxicity because of the use of thimerosal as a preservative in the HBIG preparation.¹¹⁴ In one case, a 44 year-old man received 250 mL of HBIG (containing about 30 mg of thimerosal) over 9 days following liver transplantation.¹¹⁴ He developed speech difficulties, tremor, and chorea. His whole blood mercury concentration was 104 $\mu\text{g/L}$ (normal $<10 \mu\text{g/L}$). Increased mercury concentrations in both preterm and term infants, following immunizations with thimerosal-containing hepatitis B vaccine, have also generated much concern and led to the call to reduce or eliminate the mercury content of vaccines.^{64,184}

DISINFECTANTS

Formaldehyde

Formaldehyde is a water-soluble, highly reactive gas at room temperature. Formalin consists of an aqueous solution of formaldehyde, usually containing approximately 37% formaldehyde and 12% to 15% methanol. Formaldehyde is irritating to the upper airways, and its odor is readily detectable at low concentrations. Lethality in adults may follow ingestion of as little as 30 to 60 mL of formalin.⁴⁷

Formerly used as a disinfectant and fumigant, its role as a disinfectant is now largely confined to the disinfection of hemodialysis machines. Nonetheless, formaldehyde has many other applications. Formaldehyde is widely used in construction including the wood processing and the manufacturing of furniture, textiles, and carpeting.⁹⁶ Health care workers are probably most familiar with the use of formaldehyde as a tissue fixative and embalming agent. Medical students are routinely exposed to formalin in the anatomy laboratory.¹⁵⁹

Exposure to formaldehyde, a potent caustic, may result in both local and systemic symptoms, causing coagulation necrosis, protein precipitation, and tissue fixation. Ingestions of formalin may result in significant gastric injury, including hemorrhage, diffuse necrosis, perforation, and stricture.^{3,11} The most extensive damage appears in the stomach, with only occasional involvement of the small intestine and colon.²⁰⁷ Chemical fixation of the stomach may occur. Esophageal involvement is not very prominent, and, if present, is usually limited to its distal segment.

The most striking and rapid systemic manifestation of formaldehyde poisoning is metabolic acidosis, resulting both from tissue injury and from the conversion of formaldehyde to formic acid. The patient may present with profound acidemia, accompanied by a large anion gap. Although the methanol component of the formalin solution is readily absorbed and has resulted in methanol concentrations as high as 40 mg/dL,^{22,47} the rapid metabolism of formaldehyde to formic acid appears to be responsible for much of the acidosis (Chap. 109).

Clinical Effects. Patients presenting after formalin ingestions complain of the rapid onset of severe abdominal pain, which may be accompanied by vomiting and diarrhea. Altered mental status and coma usually follow rapidly. Physical examination may demonstrate epigastric tenderness, hematemesis, cyanosis, hypotension, and tachypnea. Hypotension may be profound with decreased myocardial contractility, as well as hypovolemic shock, contributing to the cardiovascular instability.^{77,191} Early endoscopic findings include ulceration, necrosis, perforation, and hemorrhage of the stomach, with infrequent esophageal involvement. Chemical pneumonitis occurs after significant inhalational exposure.¹⁵³ Intravascular hemolysis is described in hemodialysis patients whose dialysis equipment contained residual formaldehyde after undergoing routine cleaning.^{145,157}

Occupational and environmental exposure to formaldehyde receives considerable attention. In particular, there is concern over the potential off-gassing of formaldehyde from the widely used urea formaldehyde building insulation and particle boards.¹⁴² Headache, nausea, skin rash, sore throat, nasal congestion, and eye irritation are associated with the use of these polymers.³⁹ Formaldehyde, at concentrations as low as 1 ppm, may cause significant irritation to mucous membranes of the upper respiratory tract and conjunctivae.^{81,113} Formaldehyde is also a potential sensitizer for immune-mediated reversible bronchospasm.⁷⁴ The exact immunologic mechanism is not yet elucidated, although it is likely that formaldehyde acts as a hapten. In addition, formaldehyde is thought to be a dermal sensitizer.¹⁸¹

Concerns about the health effects from the off-gassing of formaldehyde in trailers used by the Federal Emergency Management Agency (FEMA) after Hurricane Katrina illustrates the potential public health issues related to low-level formaldehyde exposure.¹¹⁷ A Center for Disease Control (CDC) investigation revealed that air formaldehyde concentrations in closed, unventilated trailers are, in fact, high enough to cause acute symptoms in some people.⁴ Long term effects after these exposures remain undefined.

Both animal and human data suggest that formaldehyde exposure is associated with an increased incidence of nasopharyngeal carcinoma.^{2,70,148,167} Although its role in the pathogenesis of cancer in humans has been the subject of much debate,^{32,121} the International Agency for Research on Cancer (IARC) classifies formaldehyde as a Group 1, known, carcinogen.

Management. The immediate management of a patient who has ingested formalin includes dilution with water. Although such an approach may be useful in reducing the caustic effect, strong evidence for a beneficial result is lacking. Gastric aspiration with a small-bore nasogastric tube may limit systemic absorption. The role of activated charcoal is not studied, and it probably should not be used if endoscopy is considered likely. Significant acidemia should be treated with sodium bicarbonate and folinic acid (Chap. 109). Immediate hemodialysis may remove the accumulating formic acid as well as the parent molecules, formaldehyde, and methanol.⁴⁷ Independent treatment for methanol toxicity may be indicated (Antidotes in Depth: A30 and A31). Early endoscopy is recommended for all patients with significant GI symptoms to assess the degree of burn injury. Surgical intervention may be required for those with suspected severe burns and/or perforation.²⁰⁷ Emergent gastrectomy, as well as late surgical intervention to relieve formaldehyde induced gastric outlet obstruction, is infrequently required.^{71,99}

Phenol

Phenol, also known as carbolic acid, is one of the oldest antiseptics. It is rarely used as an antiseptic today, secondary to its toxicity, and has been replaced by the many phenolic derivatives. Currently, phenol is used as a disinfectant, chemical intermediary, and nail cauterizer. The last application uses a highly concentrated 89% solution. Phenol is also a component (0.1%–4.5%) of various lotions, ointments, gels, gargles, lozenges, and throat sprays.⁶⁸ Campho-Phenique and Chloraseptic

contain 4.7% and 1.4% phenol, respectively. Although many cases of phenol poisoning were reported in the past, acute oral overdoses of phenol containing solutions are uncommon today.⁶⁰

Phenol acts as a caustic causing cell wall disruption, protein denaturation, and coagulation necrosis. It also acts as a central nervous system (CNS) stimulant. Intentional ingestion of concentrated phenol, ingestion of phenol-containing water, occupational exposure to aerosolized phenol, dermal contact, and parenteral administration may all result in symptomatic phenol poisoning. Phenol demonstrates excellent skin penetrance.¹⁵ Severe dermal burns from phenol have resulted in systemic toxicity, even death within minutes to hours.^{15,106} Parenteral administration of phenol has also resulted in death. The lethal oral dose may be as little as 1 g.⁸³

Clinical Effects. Clinical manifestations can be divided into local and systemic symptoms. Systemic symptoms from gastrointestinal (GI) or dermal absorption of phenol are usually more dangerous than the local effects. Manifestations of systemic toxicity include CNS and cardiac symptoms. CNS effects include central stimulation, seizures, lethargy, and coma.⁶³ In a study of patients who had ingested Creolin (26% phenol), CNS symptoms predominated.¹⁸³ Of the 52 patients who were evaluated at the hospital, 9 developed lethargy and 2 developed coma. Seizures were not reported. Cardiac symptoms from phenol include tachycardia, bradycardia, and hypotension.⁶³ Parenteral absorption of 10 mL concentrated 89% phenol resulted in hypoxemia, ARDS, pulmonary nodular opacities, and AKI requiring intubation and hemodialysis.⁶² This last case was associated with a phenol concentration of 87 mg/dL (normal <2 mg/dL).

Other systemic symptoms that may develop include hypothermia, metabolic acidosis, methemoglobinemia, and rabbit syndrome.^{83,93} Rabbit syndrome is most commonly observed as a distinctive extrapyramidal effect from antipsychotic drugs and is characterized by fine rapid repetitive movements of the perioral musculature resembling a rabbit's chewing movements. Increased acetylcholine release and a relative dopaminergic hypofunction may explain the development of rabbit syndrome after phenol exposure.⁹³

Local toxicity to the GI tract from the ingestion of phenol may result in nausea, painful oral lesions, vomiting, bloody diarrhea, dark urine, and severe abdominal pain.^{8,91} Serious GI burns are uncommon, and strictures are rare. White patches in the oral cavity may be detected. In the Creolin study cited above, only 1 of 17 patients who underwent endoscopy had a significant esophageal burn.¹⁸³ Dermal exposures to phenol usually result in a light-brown staining of the skin. Excessive dermal absorption of phenol during chemical peeling procedures is associated with dysrhythmias and many of the other symptoms.^{196,201}

Markedly elevated blood and urine concentrations of phenol may be detected after ingestion, or dermal absorption, of phenol and phenol-containing compounds (eg, Campho-Phenique).^{15,83}

Management. When phenol is mixed with water, a bilayer with unique properties is created that makes it difficult to remove from tissues. A variety of treatments have been suggested for dermal and gastric decontamination of phenol. A study using a rat model showed that cutaneous decontamination with a low-molecular-weight polyethylene glycol solution decreased mortality, systemic effects, and dermal burns.²¹ Although this study suggested that polyethylene glycol (PEG) was superior to water as a decontamination agent, a subsequent study using a swine model could not demonstrate a difference between these two therapies.¹⁵⁶ In another swine model, PEG 400 and 70% isopropanol were both superior to water washes and equally effective in decreasing dermal burn.¹²⁸ Given the lack of definitive efficacy data, either low-molecular-weight PEG, for example, PEG 300 or 400 (not to be confused with high-molecular-weight PEG that is used for whole-bowel irrigation), or high flow water is currently recommended for dermal irrigation and careful gastric decontamination. Isopropanol could also be considered as another treatment for dermal decontamination. Endoscopic evaluation, as needed to determine the extent of GI injury, and good supportive care are also recommended.

Substituted Phenols and Other Related Compounds

Hexachlorophene (pHisoHex), a trichlorinated bis-phenol, is considered generally less tissue-toxic than phenol. During the 1970s, an association was observed between repetitive whole-body washing of premature infants with 3% hexachlorophene and the development of vacuolar encephalopathy and cerebral edema.¹²² There were also multiple reports of significant neurologic toxicity and death in children who became toxic after ingesting hexachlorophene.⁷⁶ In addition, fatalities also occurred after patients absorbed substantial amounts of hexachlorophene during the treatment of burn injuries.²⁸ The use of hexachlorophene has declined significantly.

Clinical Effects. pHisoDerm contains sodium octylphenoxyethoxyethyl ether sulfonate and lanolin, and is a safe antiseptic. Irritative effects (nausea, vomiting, diarrhea) would be the main adverse effects with ingestions.

In a study of poisoning admissions to Hong Kong hospitals, the ingestion of Dettol liquid, a household disinfectant that contains 4.8% chloroxylenol, 9% pine oil, and 12% isopropanol, accounted for 10% of admissions.²⁵ Aspiration (perhaps, in part, because of the pine oil) occurred in 8% of these patients, resulting in upper airway obstruction, pneumonia, and acute respiratory distress syndrome. More common symptoms included nausea, vomiting, sore mouth, sore throat, drowsiness, abdominal pain, and fever. Dermal contact with Dettol may result in full-thickness chemical burns.⁴⁰

Cresol, a mixture of three isomers of methylphenol, has better germicidal activity than phenol and is a commonly used disinfectant. Exposure to concentrated cresol may result in significant local tissue injury, hemolysis, AKI, hepatic injury, and CNS and respiratory depression.^{40,69,94,206} Phenol concentrations, as well as cresol concentrations, serve as markers of exposure.²⁰⁶

Management. Treatment is mainly supportive.

Quaternary Ammonium Compounds

Quaternary ammonium compounds, positively charged compounds where four organic groups are linked to a nitrogen atom (NR^{4+}), are a type of cationic surfactant (surface-active agent) that are used as disinfectants, detergents, and sanitizers. Chemically, the quaternary ammonium compounds are synthetic derivatives of ammonium chloride, and structurally similar to other quaternary ammonium derivatives, such as carbamate cholinesterase inhibitors and neuromuscular blockers. Other cationic surfactants include the pyridinium compounds and the quinolinium compounds. Benzalkonium chloride (Zephiran) was one of the most commonly employed quaternary ammonium compounds in the past. Many newer quaternary ammonium compounds have supplanted its use. However, nebulized solutions used for the treatment of asthma, including albuterol and ipratropium bromide, may contain small amounts of benzalkonium chloride.

Clinical. Quaternary ammonium compounds are usually less toxic than phenol or formaldehyde. Most of the infrequent complications that are described result from ingestions of benzalkonium chloride. Complications of these ingestions include burns to the mouth and esophagus, CNS depression, elevated liver enzyme concentrations metabolic acidosis, and hypotension.^{79,140,198} Paralysis is also occasionally described as a complication of these ingestions and is presumably a result of cholinesterase inhibition at the neuromuscular junction.⁶⁰ Chronic inhalational exposure is associated with occupational asthma.¹⁶ Topical use of the quaternary ammonium compounds can cause contact dermatitis.¹⁷⁸ Ingestion of a 2.25% ammonium chloride solution marketed as a bacteriostatic algae and odor humidifier treatment resulted in serious gastrointestinal and pulmonary injury.⁶⁶

Ingestions of other cationic surfactants, such as the pyridinium agent cetrymonium bromide (Cetrimide), are associated with caustic burns to the mouth, lips, and tongue.¹³⁰ Peritoneal irrigation with cetrymonium bromide can produce metabolic abnormalities, hypotension, and methemoglobinemia.^{9,127} Intravenous administration of cetrimide produced cardiac arrest, hemolysis, and muscle paralysis.⁵⁶

Management. Treatment recommendations following the ingestion of the quaternary ammonium compounds and other cationic surface-active agents are similar to those for other potentially caustic ingestions. Emergency department evaluation should be considered for all patients who ingest more than a taste of a dilute (less than 1%) solution. Therapy is mainly supportive. Endoscopy may be warranted if symptoms suggest the possibility of a burn injury.

STERILANTS

Ethylene Oxide

Ethylene oxide ($\text{C}_2\text{H}_4\text{O}$) is a gas that is commonly used to sterilize heat-sensitive material in health care facilities. Unlike antiseptics and disinfectants, which generally do not exhibit full sporicidal activity, sterilants, such as ethylene oxide, inactivate all organisms. Ethylene oxide is also used in the synthesis of many chemicals, including ethylene glycol, surfactants, rocket propellants, and petroleum demulsifiers, and has been used as a fumigant. Ethylene oxide has a cyclic ester structure that acts as an alkylating agent, reacting with most cellular components, including DNA and RNA.

Medical attention regarding ethylene oxide toxicity has centered on its mutagenic and possible carcinogenic effects.¹⁰¹ Approximately 270,000 workers (including 96,000 hospital workers) in the United States are at risk for occupational exposure to ethylene oxide.¹⁸⁷ Retrospective studies suggest a possible excess incidence of leukemia and gastric cancer in ethylene oxide exposed workers.^{80,187} These studies are inconclusive, and the carcinogenicity of ethylene oxide remains subject to debate. It is also suggested that an increased incidence of spontaneous abortions may be associated with occupational exposure to ethylene oxide.⁷³

Clinical Effects. The acute toxicity of ethylene oxide is mainly the result of its irritant effects. Conjunctival, upper respiratory tract, GI, and dermal irritation may occur. Dermal burns from acute exposure to ethylene oxide are reported. Acute exposure to a broken ethylene oxide ampule by a 43 year-old recovery room nurse resulted in nausea, lightheadedness, malaise, syncope, and recurrent seizures.¹⁷⁰ There were no long-term complications. In another case of acute exposure, coma was followed by an irreversible parkinsonism.¹⁰

Chronic exposure to high concentrations of ethylene oxide may cause mild cognitive impairment and motor and sensory neuropathies.^{20,61,139} The risk of cancer with occupational exposure is low.^{31,186,192}

Management. Treatment for patients with ethylene oxide exposure is supportive.

Glutaraldehyde

Glutaraldehyde is a liquid solution used in the cold sterilization of nonautoclavable endoscopic, surgical, and dental equipment. It is also employed as a tissue fixative, embalming fluid, preservative, and tanning agent, in radiographic solutions, and in the treatment of warts.⁵⁸ Glutaraldehyde ($C_5H_8O_2$) is a dialdehyde with two active carbonyl groups that is less volatile than formaldehyde. It kills all microorganisms, including viruses and spores. The germicidal ability of glutaraldehyde results from the alkylation of sulfhydryl, hydroxyl, carboxyl, and amino groups, within microbes interfering with RNA, DNA, and protein synthesis.¹⁶⁹ It is prepared as a 2% alkaline solution in 70% isopropanol (Cidex). Health care workers may be exposed to glutaraldehyde vapors when equipment is processed in poorly ventilated areas, or in open immersion baths or after spills. Under these circumstances, the evaporation of glutaraldehyde may result in the increase in ambient air concentrations that may easily exceed recommended limits. Approximately 35,000 workers are occupationally exposed to glutaraldehyde.¹⁵² Patients may be exposed when diagnostic instruments are inadequately rinsed following cold sterilization with glutaraldehyde.

Clinical. Clinical signs and symptoms are thought to be comparable to those of formaldehyde exposure, although human toxicity data are limited. Animal studies show that the inhalational and dermal toxicity of glutaraldehyde are comparable to those of formaldehyde at equivalent doses.¹⁹⁰

Glutaraldehyde is a mucosal irritant. Coryza, epistaxis, headache, asthma, chest tightness, palpitations, tachycardia, and nausea are all associated with glutaraldehyde vapor exposure.^{14,33,136,146} Occupational asthma, contact dermatitis, and ocular inflammation may also occur.^{38,144,174} Colitis is reported following the use of endoscopes contaminated with residual glutaraldehyde solution.¹⁷⁶ Patients with glutaraldehyde induced colitis typically present with fever, chills, severe abdominal pain, bloody diarrhea, and an elevated white blood cell count blood within 48 hours after colonoscopy or sigmoidoscopy.

The IARC has not ranked the carcinogenic potential of glutaraldehyde.

Management. Treatment recommendations are similar to those for patients with formaldehyde exposure. Prompt removal from the exposure is essential. Copious irrigation with water provides adequate dermal decontamination. Severe inhalational exposures may require hospital admission for observation, supportive care, and treatment of bronchospasm.

In recent years, some hospitals have started using ortho-phthalaldehyde (OPA) or a mixture of hydrogen peroxide and peracetic acid as alternatives to glutaraldehyde for high-level disinfection.¹⁶³ These alternative disinfectants do not appear to have the pulmonary or dermal sensitizing properties associated with glutaraldehyde, although they may still cause some irritation to skin and mucus membranes.¹⁶³

OTHER PRODUCTS

Boric Acid

Boric acid is an odorless, transparent crystal, although it is most commonly available as a finely ground white powder. It is also available as a 2.5% to 5% aqueous solution. Boric acid (H_3BO_3), prepared from borax (sodium borate; $Na_2B_4O_7 \cdot 10 H_2O$), was first used as an antiseptic by Lister in the late 19th century. Although used extensively over the years for antiseptics and irrigation, boric acid is only weakly bacteriostatic. As a result of its germicidal limitations and its inherent toxicity, boric acid is nearly obsolete in modern antiseptic therapy. Nonetheless, it continues to be used as an antimicrobial to treat such conditions as vulvovaginal candidiasis.¹⁵⁵ Boric acid is also employed in the treatment of cockroach infestation and as a soap, contact lens solution, toothpaste, and food preservative.⁶⁵

Boric acid is readily absorbed through the GI tract, wounds, abraded skin, and serous cavities. Absorption does not occur through intact skin. Boric acid is predominantly eliminated unchanged by the kidney. Small amounts are also excreted into sweat, saliva, and feces.⁵⁷ Boric acid is concentrated in the brain and liver.

The exact mechanism of action of toxicity remains unclear. Although it is an inorganic acid, it does not behave as a caustic. Local effects are limited to tissue irritation.

Over the years, boric acid has developed a reputation as an exceptionally potent toxin. This reputation was derived in great part from a series of reports involving neonatal exposures to boric acid resulting in high morbidity and mortality. Life threatening toxicity resulted from the repetitive topical application of boric acid for the treatment of diaper rash or the use of infant formulas unintentionally contaminated with boric acid.^{57,205} Fatality rates greater than 50% were reported in some series.²⁰⁵ Although infants appear to be the most sensitive to the toxic effects of boric acid, many cases of significant toxicity are also reported in adults. These cases date predominantly from the time when boric acid was widely used as an irrigant. Routes of exposure to boric acid, resulting in fatalities, include wound irrigation, pleural irrigation, rectal washing, bladder irrigation, and vaginal packing.¹⁹⁷

Clinical Effects. Classic boric acid poisoning usually involves multiple exposures over a period of days.

Gastrointestinal, dermal, CNS, and renal manifestations predominate. The initial symptoms—nausea, vomiting, diarrhea, and occasionally crampy abdominal pain—may be confused with an acute gastroenteritis. At times, the emesis and diarrhea are greenish blue.²⁰⁵ Following the onset of GI symptoms, the majority of patients develop a characteristic intense generalized erythroderma.²⁰⁵ This rash, described as producing a “boiled lobster” appearance, may appear indistinguishable from toxic epidermal necrolysis or staphylococcal scalded skin syndrome in the neonate.^{115,168} The rash may be especially noticeable on the palms, soles, and buttocks.⁵⁷ Typically, extensive desquamation takes place within 1 to 2 days. On occasion, prominent mucous membrane involvement of the oral cavity and conjunctivae is also apparent.²⁰⁵ At about the time of the development of the erythroderma, patients, particularly young infants, may develop prominent signs of CNS irritability, resembling meningeal irritation. Seizures, delirium, and coma can occur.⁵⁷ AKI is common, both a result of the renal elimination of this compound and prerenal azotemia from GI losses.⁵⁷ Other complications of boric acid poisoning include hepatic injury, hyperthermia, and cardiovascular collapse. The abandonment of boric acid as an irrigant and particularly its removal from the nursery setting have led to a marked decrease in the incidence of significant boric acid poisoning.

Two retrospective studies on boric acid ingestions suggest that a single acute ingestion of boric acid is generally quite benign.^{108,110} In these studies, 79% to 88% of patients remained asymptomatic. Symptoms, when present, primarily consist of GI irritative symptoms, such as nausea and vomiting. None of the 1184 patients in these two studies manifested the generalized erythroderma so commonly described in previous reports. Central nervous system manifestations of acute overdose were infrequent and limited to occasional lethargy and headache. Renal toxicity did not occur following single acute ingestions.

Fatalities from massive acute ingestion of boric acid have been reported in both unintentional ingestions in children and intentional ingestions in adults.^{65,162} Fatality resulted from a single ingestion of 2 cups (280 g) of boric acid crystals by a 45 year-old man. Signs and symptoms on presentation (2 days after ingestion) included nausea, vomiting, green diarrhea, lethargy, hypotension, AKI, and a prominent “boiled lobster” rash on his trunk and extremities. In another case, the ingestion of 30 g of boric acid by a 77 year-old man resulted in similar symptoms and death 63 hours postingestion, despite hemodialysis.⁸⁸ The diagnosis of boric acid poisoning can be confirmed with the measurement of blood or serum boric acid concentrations (normal = 1.4 nmol/mL), but this test is not routinely available.

Long-term chronic exposure to boric acid results in alopecia in adults and seizures in children.¹³⁸ A 32 year-old woman who chronically ingested mouthwash containing boric acid over a 7-month period developed progressive hair loss.¹⁸⁹ The chronic application of a borax and honey mixture to pacifiers resulted in the development of recurrent seizures in nine infants, which resolved after the mixture was withheld.^{59,138}

Management. Treatment of boric acid toxicity is mainly supportive. Activated charcoal is not recommended because of its relatively poor adsorptive capacity for boric acid.⁴¹ Since boric acid has a low molecular weight and relatively small volume of distribution, in cases of massive oral overdose or AKI, hemodialysis, or perhaps exchange transfusion in infants, may be helpful in shortening the half-life of boric acid.^{34,110,134,194} Although forced diuresis is suggested to enhance renal elimination, this is highly unlikely to be successful and the risks outweigh the benefits.¹⁹⁵

Chlorates

Sodium chlorate is a strong oxidizer. At one time, the chlorate salts, sodium chlorate and potassium chlorate, were used as medicinals to treat inflammatory and ulcerative lesions of the oral cavity and could be found in various mouthwash, toothpaste, and gargle preparations.¹⁸⁵ Although their use as local antiseptics is obsolete, chlorates are used as herbicides and in the manufacture of matches, explosives, and dyestuffs.⁸⁹ More recent cases of chlorate poisoning resulted from the ingestion of sodium chlorate containing weed killers, or dispensing errors that confused sodium chlorate with sodium sulfate or sodium chloride.⁸⁹ Sodium chlorate in the form of white crystals has also been mistaken for table sugar.⁷² A case of significant toxicity from the inhalation of atomized chlorates is also reported.⁸⁹

Sodium chlorate is rapidly absorbed from the GI tract and eliminated predominantly unchanged from the kidneys.⁹⁰ Its systemic effects are chiefly hematologic and renal. The major mechanism of toxicity of chlorate is its ability to oxidize hemoglobin and increase red blood cell membrane rigidity.¹⁷⁹ Consequently, significant methemoglobinemia and hemolysis may result. Chlorates may also be directly toxic to the proximal renal tubule.¹⁰³ The hemolysis and the resultant hemoglobinuria may secondarily cause disseminated intravascular coagulation and potentiate renal toxicity. The worsening renal function is especially problematic because of its adverse effect on chlorate elimination. The methemoglobinemia may be severe and cause significant hypoxic stress. Methemoglobinemia may occur prior to or after the development of hemolysis.^{137,188} Chlorates may also act locally as a GI irritant and cause mild CNS depression after absorption.⁶⁰

Clinical. Clinical signs and symptoms of chlorate poisoning usually begin 1 to 4 hours after ingestion.⁹⁷ The earliest symptoms are GI, including nausea, vomiting, diarrhea, and crampy abdominal pain. Subsequently, the patient may exhibit cyanosis from the methemoglobinemia and black-brown urine from the hemoglobinuria. Obtundation and anuria may ensue.

Laboratory studies may show methemoglobinemia, anemia, Heinz bodies, ghost cells, fragmented spherocytes, metabolic acidosis, decreased platelet count, and abnormal coagulation.⁵¹ Hyperkalemia may be particularly problematic if the patient ingests potassium chlorate preparations.¹³³ In a case of chlorate poisoning from the ingestion of 120 potassium chlorate–containing matchsticks, an MRI revealed symmetric abnormal signal intensity within the deep gray matter and medial temporal lobes.¹³³ This finding can be explained by the increased vulnerability to oxygen deprivation of the basal ganglia. Follow-up MRI two months later was normal.

Management. Treatment of a patient with a significant chlorate ingestion should include orogastric lavage and the use of activated charcoal.⁷² It has been suggested that administration of sodium thiosulfate may inactivate the chlorate ion by reducing it to the chloride ion,⁷² but an in vitro study did not confirm this hypothesis.¹⁸⁸ The utility of methylene blue in the treatment of symptomatic chlorate induced methemoglobinemia has been questioned as a consequence of the inactivation by chlorates of glucose–6-phosphate dehydrogenase, an enzyme that is required for methylene blue to effectively reduce methemoglobin.^{179,188} More recent experience suggests that early use of methylene blue prior to the onset of hemolysis may be useful in the treatment of chlorate induced methemoglobinemia.^{19,104} Exchange transfusion, peritoneal dialysis, and hemodialysis have also been advocated in the treatment of patients with severe chlorate poisoning.^{137,188} Because the chlorate ion is easily dialyzable, hemodialysis is capable of removing this xenobiotic as well as treating any concomitant AKI that may have developed.^{89,97,103}

SUMMARY

- A chemically diverse group of antiseptics, disinfectants, and sterilants exist.
- Many of the more toxic xenobiotics, such as iodine, phenol, and chlorates, are no longer commonly used as cleansers but may still be available in some settings.
- Formaldehyde exposures, although also uncommon, can also cause significant toxicity.
- Frequently employed antiseptics, such as chlorhexidine, pHisoDerm, and many of the currently used quaternary ammonium compounds, have a relatively limited toxicity.
- Ingestions of the iodophors do not usually cause significant toxicity, but absorption through other routes may produce significant adverse effects. Ingestion of hydrogen peroxide, particularly the more concentrated formulations, may result in life threatening injuries.

105 CAMPHOR AND MOTH REPELLENTS

Hong K. Kim

Many different products have been used as moth repellents. In the United States, paradichlorobenzene has largely replaced both camphor and naphthalene as the most common active component of moth repellent and moth flakes because of its lower toxicity. However, life threatening camphor and naphthalene toxicity still occurs, especially in immigrant communities, from exposures to imported camphor or naphthalene-containing products.^{3,49,64,80} Therefore, toxicity of camphor, naphthalene, and paradichlorobenzene should be considered when evaluating possible exposure to moth repellents.

CAMPBOR

History and Epidemiology

Camphor (2-bormanone, 2-camphonone), a cyclic ketone of the terpene group, is an essential oil originally distilled from the bark of the camphor tree, *Cinnamomum camphora*. Today, camphor is synthesized from the hydrocarbon pinene, a derivative of turpentine oil. Camphor has been used for centuries as an aphrodisiac, contraceptive, abortifacient, suppressor of lactation, analeptic, cardiac stimulant and antiseptic.^{43,55,57,61,72,96,109} Camphor is a commonly used ingredient found in many nonprescription remedies for cold symptoms, cold sores, and in muscle liniments.^{2,75,77,93,97} Camphor is also rarely abused as a stimulant.⁶⁹

Camphorated oil and camphorated spirits contain varying concentrations of camphor. Historically, most camphorated oil was prepared as a 20% weight (of solute) per weight (of solvent) (w/w) solution of camphor with cottonseed oil, and most camphorated spirits contained 10% w/w camphor with isopropyl alcohol. Toxicity and death following ingestion of camphorated oil, which was frequently confused with castor oil and cod liver oil, prompted the FDA to ban the nonprescription sale of camphorated oil in the United States in 1980.^{11,61,76,120,125} The FDA ban of camphorated oil was followed by a restriction on camphor content in 1983, limiting the camphor concentration to less than 11% in nonprescription camphor containing products in the United States.¹²⁶ However, camphorated oil is still used as an herbal remedy and muscle liniment, and products containing greater than 11% camphor can still be purchased in local stores of various ethnic communities in the United States and in other countries.^{35,49,64,117}

Common camphor-containing products include ointments often used for herpes simplex on the lips (usually <1% camphor), muscle liniments, rubefacients (usually 4%–7% camphor), and camphor spirits (usually 10% camphor). Paregoric, camphorated tincture of opium, contains a combination of anhydrous morphine (0.4 mg/mL), ethanol (46%), and benzoic acid (4 mg/mL) but only a small amount of camphor.⁶⁸ For industrial uses, camphor can be purchased legally in the United States and contains up to 100% camphor. Occupational exposures to camphor occur during the manufacture of plastic, celluloid, lacquer, varnish, explosives, embalming fluids, and numerous pharmaceuticals and cosmetics.⁶⁸

Although products containing lower concentrations of camphor are implicitly safer, life threatening toxicity and death may still result from misuse or intentional overdose. Most reported cases of acute camphor poisoning are unintentional ingestions of camphor containing products mistaken for other medications or therapeutic misadventures from nonprescription products, including home remedies.^{3,11,35,49,61,64,100,118,121} According to data obtained by the American Association of Poison Control Centers (AAPCC), there are approximately 13,000 exposures to camphor containing

products each year with a majority of the exposure, approximately 80%, occurring in children under the age of 5 years (Chap. 136).

Prior to FDA ban of camphorated oil and restriction on camphor content in nonprescription products, high incidence of systemic symptoms and seizures, 46% and 20% respectively, were reported in children under 5 years of age.¹²⁹ A group of 530 camphor exposure cases showed that among all reported cases, 15% presented with systemic symptoms, and 4% had seizures.^{42,93} Unfortunately, limited data is available with regard to the true incidence of systemic toxicity and seizure since the FDA ruling in 1983. According to AAPCC data, seven reported deaths were attributable to camphor over the past 20 years, all in adults, and at least two of which occurred in the setting of an intentional suicidal ingestions. Although a majority of the patients with unintentional exposures remain asymptomatic and do not present to the health care facility, significant morbidity from unintentional camphor exposures still occurs in children.^{3,35,49,64,80,93,97,117} The public health implication of camphor exposure in children is of great concern because of its lack of therapeutic value and its potential life threatening toxicity.

Pharmacology

Camphor is a colorless glassy solid. Its pharmacologic activity is not well studied, and its mechanism of action remains unclear. It is unlikely that camphor has therapeutic benefit as an expectorant or an antiinfective. No therapeutic benefit of camphor has been proven in any well-controlled clinical trials. Camphor may provide some local analgesic and antipruritic effects, but much safer alternatives are available for these indications.

Pharmacokinetics and Toxicokinetics

There are limited data on the pharmacokinetics and toxicokinetics of camphor. Ingestion is the most common route of exposure, resulting in significant camphor toxicity.^{3,64,69,80,93,132} However, toxicity can be observed following inhalation, intranasal instillation, intraperitoneal administration, and from transplacental transfer, resulting in fetal death.^{29,102,107,111,115,132} Dermal exposures are also reported to cause systemic toxicity.^{35,49,64,98,121} Camphor is a highly lipophilic compound that is rapidly absorbed from the gastrointestinal tract and can be detected in the blood within 15 to 20 minutes following ingestion.^{93,102} The presence of food in the stomach may delay the absorption of camphor.¹ Due to lack of experimental data, the bioavailability from each route of exposure is unknown. In an animal experiment, a peak blood camphor concentration was achieved in 90 minutes when rats were administered an oral dose of 1 g/kg.³⁴ A significant amount of camphor can be absorbed through normal skin. Dermal absorption of camphor is slow but can produce systemic toxicity up to 72 hours following exposure.^{49,64} The volume of distribution is estimated at 2 to 4 L/kg with protein binding of approximately 61%.^{68,69}

Camphor is predominantly metabolized in the liver and eliminated by the kidneys. Up to 59% of the camphor is eliminated in urine as glucuronides but unchanged camphor (<1%) and other oxidative metabolites are eliminated without glucuronidation.^{69,104,109} Five inactive meta-bolites are produced by hydroxylation of a methylene group (the predominant pathway) and reduction of the oxo group.¹⁰⁴ Inactive metabolites, 3-hydroxycamphor, 5-hydroxycamphor (major metabolite), 8-hydroxycamphor, 9-hydroxycamphor, and borneol, are either conjugated with glucuronic acid or further oxidized and eliminated by the kidneys.^{69,104} The exact site of camphor metabolism is unknown, but CYP 2A6 and NADPH-P450 reductase are known to be involved in two in vitro experiments.^{50,84} Nine other CYP enzymes (1A1, 1A2, 2B6, 2C8, 2C9, 2C19, 2C6, 2E1, and 3A4) all failed to produce detectable metabolites of camphor.⁵⁰ CYP2A6 metabolized camphor to 5-hydroxycamphor, a major camphor metabolite.⁵⁰ In humans, a plasma elimination half-life of 93 minutes and 167 minutes was reported after 200 mg of camphor was ingested by a volunteer, with Tween 80 as a solvent (10 mL) or without the solvent, respectively.⁶⁸ A comparable elimination half-life of 144 minutes was found in an animal study after an oral ingestion.³⁴ Small amounts of camphor may be eliminated by exhalation, as noted by characteristic odor in breath, but no studies have assessed the significance of this route of elimination.^{69,75}

The reported toxic dose of camphor is highly variable.^{51,61,113} A potential lethal dose of 50 to 500 mg/kg of camphor is often cited for humans.^{35,42,80,93} Yet, as little as 1 g of camphor has reportedly resulted in death in a 19 month-old infant, while up to 42 g of camphor was ingested by an adult who recovered.^{2,113} There is insufficient data to suggest a clear toxic dose range of camphor. However, there is evidence to suggest that camphor can cause life threatening toxicity at low doses (estimated exposure of 700 to 1500 mg) based on a series of case reports in both adults and children.^{29,42,75,93,113,117} Currently, the AAPCC recommends that any patient who is exposed to 30 mg/kg or more of camphor should receive emergent medical attention.⁷⁷

Workplace standards determined by the Occupational Safety and Health Administration (OSHA) has set the permissible exposure limit (PEL) at 2 mg/m³.¹²³ The American Conference of Governmental Industrial Hygienists' (ACGIH) threshold limit value (TLV) is 12 mg/m³ (2 ppm), while the short-term exposure limit (STEL) is 19 mg/m³ (3 ppm). The National Institute for Occupational Safety and Health (NIOSH) Immediately Dangerous To Life or Health Concentration (IDLH) is

200 mg/m³.¹²²

Pathophysiology

The mechanism of toxicity of camphor is unknown. Camphor is an irritant. Pathologic changes following ingestion include cerebral edema, neuronal degeneration, fatty changes, centrilobular congestion of the liver, and hemorrhagic lesions in the skin, gastrointestinal tract, and kidneys.^{35,62,113,132}

Clinical Manifestations

Exposure to camphor can often be detected by its characteristic aromatic odor (Chap. 26). Ingestion of camphor typically produces oropharyngeal irritation, nausea, vomiting, and abdominal pain. Generalized tonic-clonic seizures may be the first sign of camphor toxicity, usually occurring within 1 to 2 hours of ingestion.^{13,18} The onset of systemic toxicity, particularly CNS toxicity, can occur as early as 5 minutes after ingestion.^{29,32,75,113} Most seizures are brief and self-limited, although some patients may have a more protracted course, including status epilepticus.^{13,45,49,67,111} Delayed seizures, occurring up to 9 hours following ingestion and up to 72 hours following dermal exposure, are reported.^{49,105} Central nervous system (CNS) depression is common, but camphor rarely compromises respiratory function.^{29,68} Other neurologic manifestations include headache, lightheadedness, transient visual changes, confusion, myoclonus, and hyperreflexia.^{65,102,107} Psychiatric manifestations include agitation, anxiety, and hallucinations.^{51,65,68} Dermal effects include flushing and petechial hemorrhages.^{29,55,115} Camphor does not typically cause life-threatening cardiovascular effects, although a case of myocarditis is reported.¹⁹ Deaths are reported secondary to status epilepticus.^{16,29,77,113} Case reports suggest that acute ingestion of camphor can cause transient elevations of the hepatic aminotransferases.^{11,62,102,107,111} Chronic administration of camphor to a child caused altered mental status and elevated hepatic aminotransferases concentrations suggestive of Reye syndrome.⁶² When hepatotoxicity occurs, however, camphor does not typically produce morphologic changes in the liver characteristic of Reye syndrome. Albuminuria can also occur.¹¹³

Camphor crosses the placenta. Both fetal demise and delivery of healthy neonates are reported in mothers who experienced acute camphor toxicity from both intentional and unintentional ingestion and delivered during the following 24 hours.^{20,102,132} Specific dose-related toxicity cannot be determined from these case reports.

Inhalational and dermal exposure from camphor usually produces only mucous membrane and dermal irritation, respectively.⁴⁸

Diagnostic Testing

No specific diagnostic test is available or indicated when managing patients with camphor toxicity. Camphor and its metabolites can be identified in blood and urine.^{69,104} But these tests are not clinically useful in most cases of acute toxicity as they are not readily available and have not been shown to correlate with clinical toxicity.^{55,69,104}

Management

Patients who should be evaluated in a health care facility after an acute ingestion include those who have signs or symptoms consistent with camphor toxicity, those who have ingested more than 30 mg/kg of camphor, suicidal patients, and any patient with a significant occupational exposure.⁷⁷

Gastric decontamination is not well studied in patients with acute camphor ingestion. Camphor is rapidly absorbed in the gastrointestinal tract due to its high lipophilic property. Thus, the benefit of gastrointestinal (GI) decontamination rapidly diminishes with time following acute ingestion. Gastric decontamination may be difficult to perform at times, as GI symptoms (eg, active vomiting) are frequently encountered. Gastric lavage has been performed in patients with acute camphor ingestions, but clinical benefit of such procedure in setting of camphor toxicity is unknown.^{42,93} If lavage is deemed necessary following recent ingestion of a camphor-containing solution, nasogastric suctioning and lavage are preferable to orogastric lavage. The utility of activated charcoal in acute camphor ingestion is unknown. One animal study showed that administration of activated charcoal (2 g/kg; 2:1 activated charcoal to toxin ratio) immediately following camphor ingestion did not alter the gastrointestinal absorption of camphor.³⁴ There are no human data in support for or against the use of activated charcoal in camphor ingestions. Given the lack of data, an AAPCC consensus panel has recommended against the use of activated charcoal in patients with isolated camphor ingestions.⁷⁷

There is no antidote for camphor. Most patients survive with supportive care. Although the management of camphor induced seizures is not well studied, the first line therapy for camphor induced seizures is a benzodiazepine. Repeat doses of benzodiazepines may be needed to control seizures. If benzodiazepines fail to control seizures, other sedative-hypnotics, including pentobarbital or propofol, should be administered. Case reports suggest that most patients who develop life-threatening camphor toxicity develop symptoms within a few hours postexposure. Based on this, an observation period of at

least 4 hours following a potentially toxic ingestion of camphor is reasonable. In case reports, hemodialysis with a lipid dialysate and either hemoperfusion using an Amberlite resin or charcoal hemoperfusion successfully removed camphor.^{11,44,67,68,78} However, neither isolated lipid hemodialysis nor lipid dialysis in combination with hemoperfusion is routinely recommended or widely available.

NAPHTHALENE

History and Epidemiology

Naphthalene ($C_{10}H_8$), an aromatic bicyclic hydrocarbon, is commonly found in products such as moth repellents, toilet-bowl and diaper-pail deodorizers, and soil fumigants.¹¹⁴ It is the single most abundant component of coal tar, approximately 11% by weight, and is used in the manufacture of numerous commercial and industrial products.^{24,114} Both crude oil and refined products such as gasoline and diesel fuels contain naphthalene.

Historically, naphthalene toxicity has mainly resulted from its use as an antihelminthic and an antiseptic.¹¹² In recent years, unintentional and intentional ingestions of mothballs containing naphthalene have become the major etiology of naphthalene toxicity.^{66,73,109,116,131} A single naphthalene mothball can contain between 0.5 and 5 g of naphthalene depending on its size.⁴ Toilet-bowl and diaper-pail deodorizers containing naphthalene have also caused toxicity.^{28,139} Chronic exposure to naphthalene occurs in occupational setting with variable levels of exposure depending on the industry. The most common use of naphthalene is in the production of phthalic anhydride, a compound used in chemical feedstock.⁴⁷ Other industrial uses of naphthalene include carbamate insecticides, dye intermediates, synthetic resins, bathroom (urinal) air fresheners, fuel additives, plasticizers, and the manufacture of other chemicals.^{47,114} Naphthalene is also generated as a by-product of combustion and is present in ambient air at low concentrations.⁴⁷

Most unintentional exposures to naphthalene-containing moth repellents occur in children and do not cause life-threatening toxicity. According to data from the AAPCC, each year there are between 1500 and 2000 exposures to naphthalene. Since 1998 there has not been a naphthalene-associated death reported to AAPCC, and reports of “major toxicity” are very unusual (Chap. 136). Mothball vapors are also intentionally inhaled as a form of inhalant abuse.^{70,131}

Pharmacology, Pharmacokinetics, and Toxicokinetics

Naphthalene is a white, flakey crystalline solid with a noxious odor. Synonyms include white tar and tar camphor. Naphthalene toxicity is reported following ingestion, dermal application, and inhalation.^{30,33,36,106,127} Although the absorption of naphthalene is not well studied, highly lipid-soluble compounds may increase both oral and dermal absorption. Naphthalene metabolism is complex and varies considerably among species and different anatomical regions.²² For instance, an in vitro study using human liver microsomes showed that multiple CYP450 enzymes are involved in naphthalene metabolism: 1A1, 1A2, 1B1, 2A6, 2B6, 2C19, 2D6, 2E1, and 3A4.²⁷ On the other hand, data from animal studies showed a different group of CYP450 isoenzymes are responsible for naphthalene metabolism.⁴ Metabolic pathways involve several intermediates and generate multiple reactive metabolites: 1,2-naphthalene oxide, 1,4-naphthoquinone, 1,2-naphthoquinone, and 1,2-dihydroxy-3,4-epoxy-1,2,3,4-tetrahydronaphthalene^{4,22,23} (Fig. 105–1).

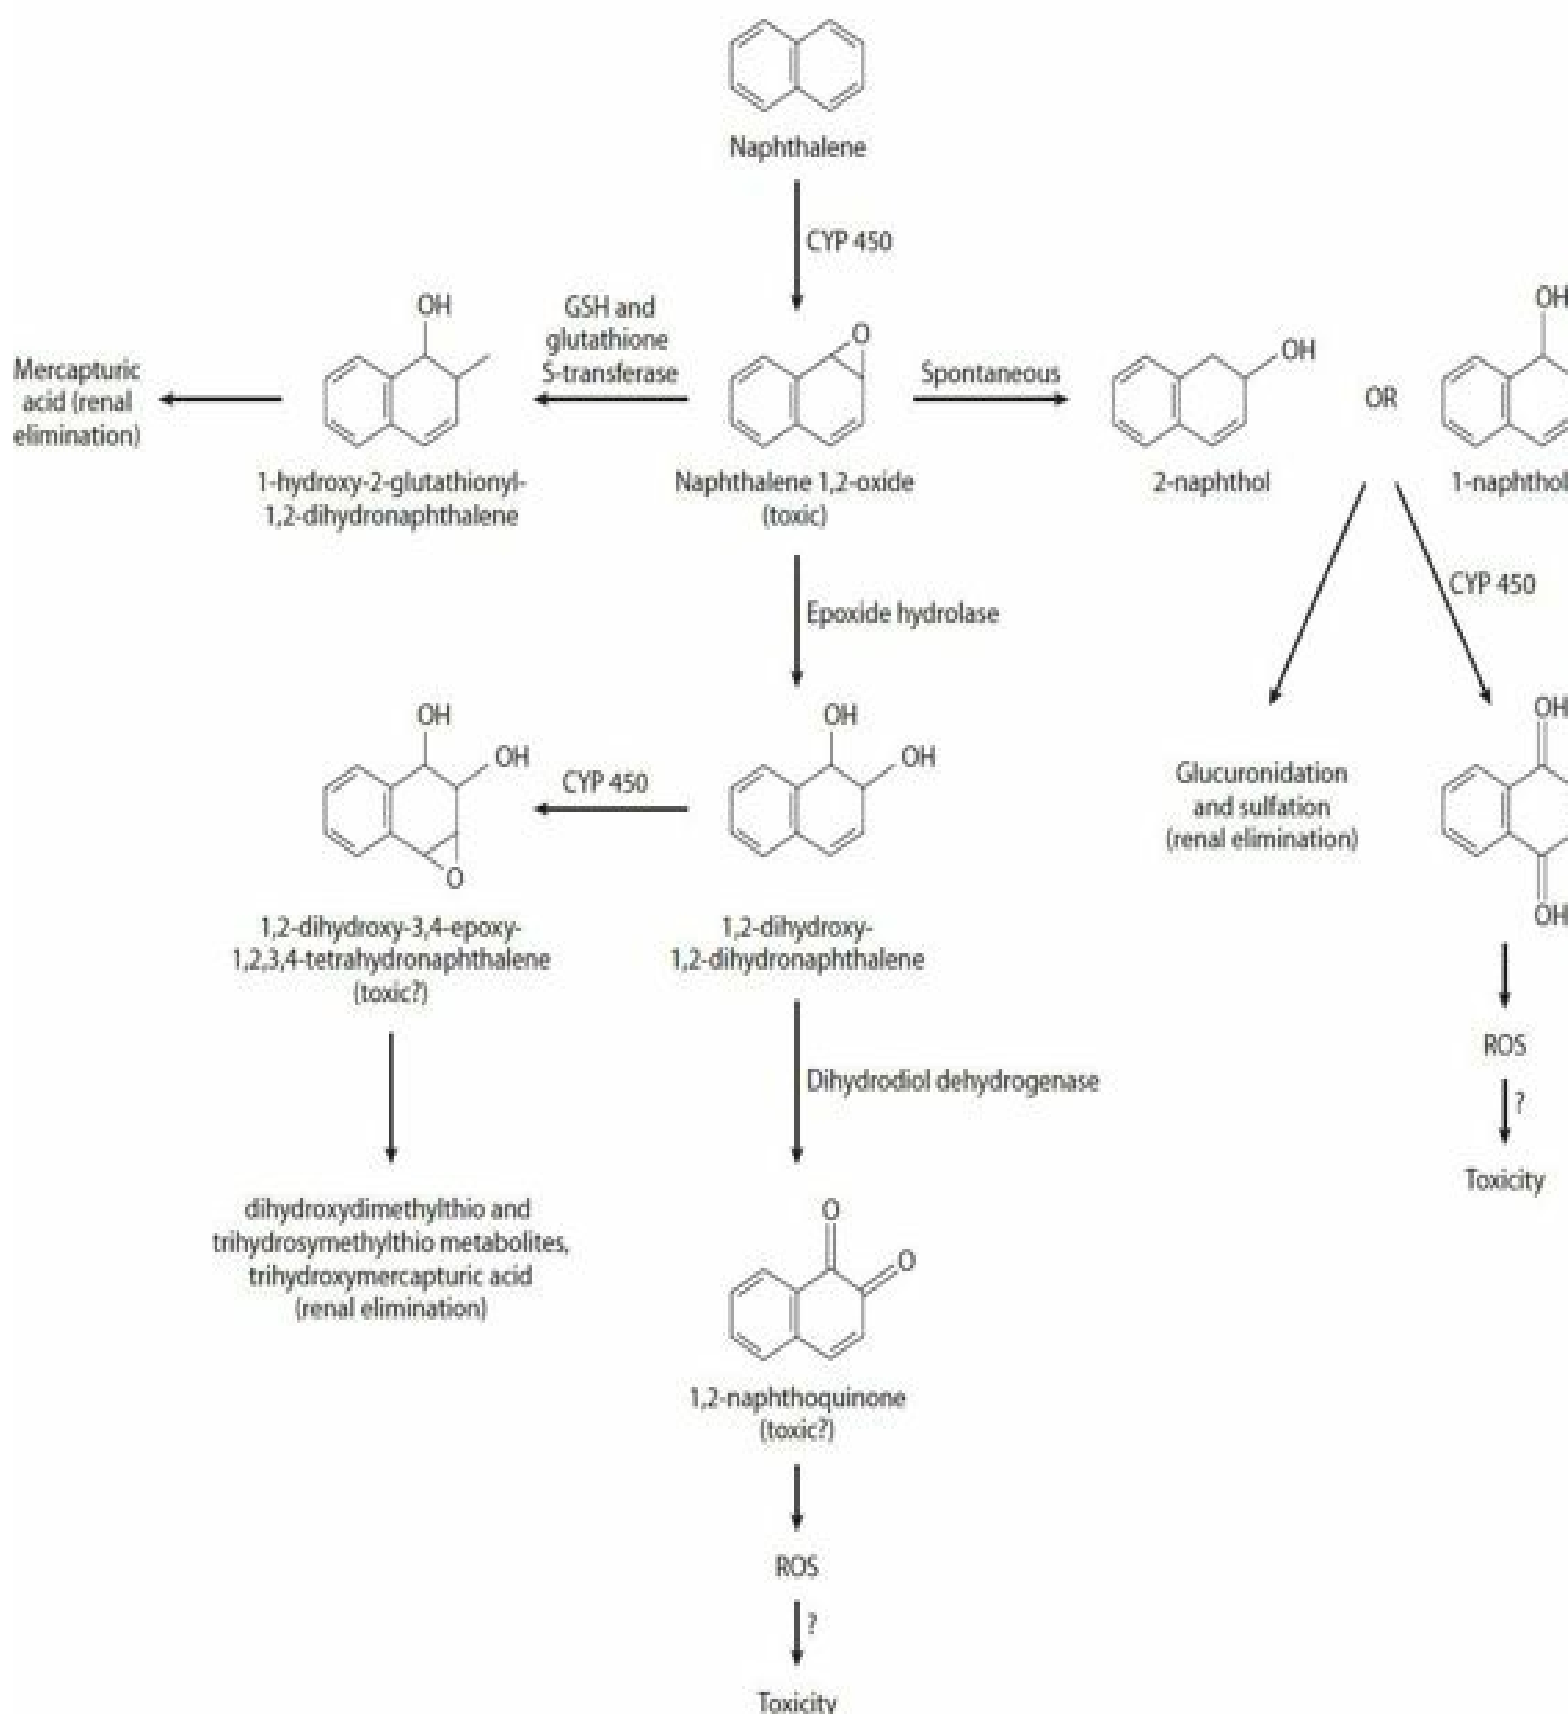

FIGURE 105–1. Hepatic metabolism of naphthalene and its respective metabolites. GSH = reduced glutathione; ROS = reactive oxygen species. (Adapted with permission from Buckpitt, et al 2002; Bogen, et al 2008; Agency for Toxic Substances and Disease Registry 2005.)

Naphthalene is initially metabolized to an unstable epoxide intermediate, 1,2-naphthalene oxide.^{4,23,114} Naphthalene 1,2-oxide can react with cellular components such as DNA and protein to form covalent adducts or can be spontaneously converted to 1-naphthol and 2-naphthol, which undergo glucuronidation or sulfation to form conjugates that are subsequently eliminated in urine.^{4,22,23} Glutathione-S-transferase and glutathione play an important role in detoxification of 1,2-naphthalene oxide by converting the reactive epoxide to nonreactive mercapturic acid metabolites.^{22,23,76} The depletion of glutathione prior to naphthalene exposure increases acute injury in lung Clara cells, one of the target organs of naphthalene toxicity in mice.^{94,95}

Reactive hepatic metabolites, 1-naphthol, 1,2-naphthoquinone, and 1,4-naphthoquinone, are cytotoxins which deplete intracellular glutathione stores and generate reactive oxygen species.^{4,114,138} They are responsible for the oxidative stress leading to naphthalene-induced hemolysis and methemoglobinemia.

The toxic amount of naphthalene reported in the medical literature is highly variable. As little as one naphthalene mothball has resulted in toxicity, including hemolysis in an infant.^{41,139} Workplace standards include the OSHA PEL, which is 50 mg/m³ (10 ppm), ACGIH TLV, which is 52 mg/m³ (10 ppm), and the ACGIH STEL, which is 79 mg/m³ (15 ppm); NIOSH IDLH is 250 ppm (US Dept of Labor OSHA).¹²³

Pathophysiology

Naphthalene-induced (via oxidative metabolites: 1-naphthol, 1,2-naphthoquinone, and 1,4-naphthoquinone) hemolysis and methemoglobinemia result when physiologic compensatory mechanisms to oxidative stress are overwhelmed. It is important to understand how oxidant stress affects erythrocytes and the normal mechanisms erythrocytes use to prevent and reverse the effects of oxidant stress.

Oxidant stressors can cause methemoglobinemia and/or hemolysis. When oxidant stress causes an iron atom from any of the four globin chains of hemoglobin to be oxidized from the ferrous state (Fe²⁺) to the ferric state (Fe³⁺), methemoglobin is formed ([Chap. 127](#)). When oxidant stress causes hemoglobin denaturation, the heme groups and the globin chains dissociate and precipitate in the erythrocyte, forming Heinz bodies. An erythrocyte with denatured hemoglobin is more susceptible to hemolysis and removal by the reticuloendothelial system ([Chap. 22](#)).

Hemolysis and methemoglobinemia can occur independently or simultaneously in patients with either normal or deficient glucose-6-phosphate dehydrogenase (G6PD) activity.^{43,58,127,139} Patients with G6PD deficiency are at increased risk for both hemolysis and methemoglobinemia following oxidant stress. Patients with G6PD deficiency are at much greater risk of hemolysis rather than methemoglobinemia due to their decreased glutathione stores.^{79,127,138} G6PD affects all races, but is most prevalent in patients of African, Mediterranean, and Asian descent. The gene that codes for G6PD is X-linked; consequently, men are affected more often than women.

Infants are also at increased risk of methemoglobinemia because fetal hemoglobin is more susceptible to the formation of methemoglobin and also because nicotinamide adenine dinucleotide phosphate (NADPH) methemoglobin reductase activity is less well developed, impairing the reduction of methemoglobin to hemoglobin.⁶³

Injuries to other organs, eyes, lungs, and liver, have been reported in animal studies after exposure to naphthalene.^{40,89,99,114,128} However, there is a significant interspecies variation in the degree of toxicity. Human data on organ toxicity beyond hematologic effects of naphthalene are limited. A few case reports link the development of cataracts to occupational exposure; however, the causal relationship remains questionable.⁸⁹ The mechanism of cataract formation may involve oxidative destruction of lens proteins.¹¹⁴ Animal studies show that oxidative stress from naphthalene results in hepatic injury by lipid peroxidation and pulmonary epithelial necrosis.^{40,99,114} However, there is no evidence to suggest that hepatotoxicity or pulmonary toxicity occurs in humans from naphthalene exposure.

Clinical Manifestations

Both acute and chronic exposures to naphthalene result in similar toxicity.^{28,86,138} Ingestion and inhalational exposures to naphthalene commonly cause headache, nausea, vomiting, diarrhea, abdominal pain, fever, and altered mental status.^{28,74,91} Dermal exposure results in dermatitis.⁴⁶

Hemolysis and methemoglobinemia usually become clinically evident, as early as 24 to 48 hours postexposure, but more typically on the third day postexposure because of the time necessary for the hepatic metabolism of naphthalene.^{33,73} Anemia secondary to hemolysis often does not reach its nadir until 3 to 5 days postexposure.^{9,119}

Signs and symptoms of hemolysis and methemoglobinemia are nonspecific and include tachycardia, tachypnea, shortness of breath, generalized weakness, decreased exercise tolerance, and altered mental status. Methemoglobinemia may produce cyanosis, whereas hemolysis may produce pallor and jaundice ([Chap. 127](#)). Renal failure is reported as a complication of naphthalene-induced hemolysis and hemoglobinuria. Naphthalene or its metabolites cross the placenta.¹² Naphthalene pica during pregnancy causes both maternal and fetal toxicity. Children born to mothers who were experiencing naphthalene toxicity at the time of delivery have developed hemolytic anemia believed to be related to the maternal naphthalene exposure.¹³⁸ Although cataracts have been reported in animals following naphthalene exposure, human data are inconclusive.⁸²

Based upon animal data on carcinogenicity, naphthalene is classified by the International Agency for Cancer Research (IARC) as a Group 2B carcinogen (possibly carcinogenic to humans) and by the EPA as a Group C possible human carcinogen.^{47,60} The data supporting human carcinogenicity of naphthalene are limited. There are several case reports of the associated exposure with laryngeal cancer in East Germany and colorectal cancer in Nigeria but causal relationship cannot

be determined.^{7,47}

Diagnostic Testing

No specific diagnostic testing is indicated, although both naphthalene and its metabolites can be identified in blood and urine. Identification of 1-naphthol and 2-naphthol in the urine can confirm exposure to naphthalene. Qualitative or quantitative testing for naphthalene or its metabolites is not clinically indicated when managing a case of an acute overdose.⁹²

The presentation of naphthalene-induced hemolysis is similar to that of hemolysis from other causes. Reticulocytosis occurs as a response to restore a normal hemoglobin concentration. Hyperbilirubinemia from hemolysis is characterized by an elevation of the unconjugated bilirubin and a relatively normal conjugated fraction. Serum haptoglobin is usually low because the haptoglobin–hemoglobin complex is cleared by the kidneys. Both the direct and indirect Coombs tests are negative in naphthalene-induced hemolytic anemia. Lactate dehydrogenase is elevated due to its release from hemolyzed red blood cells. Hemoglobinuria is suggested by a urine dipstick that reacts strongly positive for hemoglobin with a paucity or absence of red blood cells on microscopic examination of the urine sediment. Hemoglobinemia should be differentiated from myoglobinuria, which has a comparable urine sediment, by measuring the serum creatine phosphokinase, which will be elevated in patients with rhabdomyolysis and myoglobinuria.

Examination of a peripheral blood smear can suggest hemolysis before a patient develops clinical or laboratory evidence of anemia. The peripheral smear may reveal red blood cell (RBC) fragmentation (schistocytes), anisocytosis, microspherocytosis, reticulocytosis, nucleated RBCs, Blister cells, and Heinz body formation ([Chap. 22](#)). Peripheral smear abnormalities and anemia may occur within the first 24 hours following ingestion.^{28,108,138,139} Testing for G6PD activity is not routinely recommended during an acute episode of hemolysis. Reticulocytes have higher G6PD activity than do older RBCs. If G6PD activity is measured during an episode of hemolysis when many of the older RBCs have already been destroyed, the G6PD activity may be falsely disproportionately elevated or normal. It is best to delay testing for G6PD activity for a few months following an episode of hemolysis. Family members of patients with life-threatening G6PD deficiency should also be tested.

Naphthalene-induced methemoglobinemia is similar in presentation to methemoglobinemia from other xenobiotics. The percentage of methemoglobin can rapidly be determined using a cooximeter ([Chap. 127](#)).

Management

Most patients with an unintentional exposure to no more than one naphthalene containing mothball do not require medical evaluation. Patients who should be evaluated in a health care facility following an acute ingestion include those who recently ingested more than one naphthalene-containing mothball equivalent, those with signs or symptoms of toxicity, especially hemolysis and/or methemoglobinemia, those with known or suspected G6PD deficiency, all intentional ingestions, and those patients with substantial inhalational exposures, particularly those occurring in an occupational setting.

Gastrointestinal decontamination is not well studied in patients who have ingested naphthalene. Most patients with unintentional exposures do not require gastrointestinal decontamination. Administration of activated charcoal, 1 g/kg, although not of proven efficacy, is reasonable because it is considered safe. Repeat doses of activated charcoal 0.5 g/kg and/or whole-bowel irrigation with polyethylene glycol electrolyte lavage solution would only be indicated for patients with large ingestions of naphthalene who are expected to have significant ongoing gastrointestinal absorption.

Diagnostic testing within the first 24 to 48 hours postexposure may detect the onset of methemoglobinemia and/or hemolysis before a patient becomes symptomatic. Most low-risk patients who are asymptomatic within the first 24 to 48 hours postexposure and who have no laboratory evidence of hemolysis or methemoglobinemia can be managed as outpatients if reevaluation within 24 to 48 hours can be arranged. Patients who are discharged should be instructed to return if they become symptomatic. High-risk patients, patients with laboratory evidence of hemolysis and/or methemoglobinemia, and patients who cannot be reliably managed as outpatients should be admitted.

Patients with life-threatening hemolysis and anemia should be transfused with packed red blood cells. However, most healthy patients will be able to compensate for the hemolysis and will not require a transfusion. Patients with symptomatic methemoglobinemia should receive methylene blue, 1 to 2 mg/kg (0.1–0.2 mL/kg of a 1% solution) intravenously. Repeat doses may be necessary ([Antidotes in Depth: A42](#)).

PARADICHLOROBENZENE

History and Epidemiology

Paradichlorobenzene (1,4-dichlorobenzene) is widely used as a deodorizer, disinfectant, repellent, fumigant, insecticide, fungicide, and industrial solvent. Today, paradichlorobenzene is the most common component of moth repellents in the

United States. Low level exposure to paradichlorobenzene in the United States is extremely common due to environmental contamination from release of paradichlorobenzene to air by industrial facilities.⁹⁰ The primary route of human exposure is inhalation in either an occupational setting or from indoor air where paradichlorobenzene is used as a deodorizer or moth repellent.⁹⁰ Paradichlorobenzene is also found in both water and numerous food items, including pork and fresh vegetables, from environmental contamination.^{90,103,130} In 1995, a study suggested that 2,5-dichlorophenol, a metabolite of paradichlorobenzene, was detectable in the urine in 98% of the US population.⁵⁸

Most unintentional exposures to paradichlorobenzene-containing moth repellents occur in children and do not cause toxicity. According to the AAPCC data, there were no deaths and no reports of major toxicity associated with paradichlorobenzene between 1998 and 2011.

Pharmacology, Pharmacokinetics, Toxicokinetics, and Pathophysiology

Paradichlorobenzene ($C_6H_4Cl_2$) is a colorless solid with a noxious odor. It is available as pure white crystals, as a solid in combination with other chemicals, or as a liquid dissolved in volatile solvents or oil.¹⁰ The mechanism of the toxicologic effect of paradichlorobenzene has not been studied. Although rare, paradichlorobenzene toxicity is reported following ingestion and inhalation.^{59,81} Inhalation toxicokinetics reveal that in humans there is rapid distribution and accumulation in tissues, specifically in adipose tissue.^{15,26,56,137} The major route of elimination is urinary excretion followed by hepatic metabolism, with none by exhalation.^{15,137} CYP2E1, CYP1A1, and CYP1A2 convert paradichlorobenzene to its primary metabolite, 2,5-dichlorophenol, which is eliminated as either sulfated or glucuronidated conjugates.^{21,54,56}

Workplace standards include the OSHA PEL, which is 450 mg/m³ (75 ppm) time-weighted average (TWA), ACGIH TLV, which is 60 mg/m³ (10 ppm) TWA, and the ACGIH STEL, which is 675 mg/m³ (110 ppm); NIOSH IDLH is 150 ppm.¹²⁴

Clinical Manifestations

Paradichlorobenzene is considered to have less toxicity than camphor and naphthalene. However, cases of clinical toxicity from paradichlorobenzene are reported ranging from hemolytic anemia to toxic leukoencephalopathy following acute and/or chronic exposure.^{14,25,26,37,39,52,53,56,71,81,83,101,109,110,131} Although paradichlorobenzene can be absorbed following inhalation, ingestion and cutaneous exposures are the routes of exposure that lead to toxicity.^{37,39,56,83,101,131} Acute unintentional exposure to paradichlorobenzene may cause limited transient clinical effects such as nausea and vomiting, headache, and mucous membrane irritation.^{31,59} However, significant neuropsychiatric dysfunction, specifically cerebellar dysfunction, motor weakness, and cognitive decline, is reported following chronic intentional and occupational exposure.^{37,39,56,71,81,83} In most cases, neurologic and cognitive deficits associated with paradichlorobenzene developed after several months of exposure and seldom resulted in complete resolution after cessation of paradichlorobenzene exposure.^{14,56,83} Other clinical signs and symptoms from chronic exposure include pulmonary granulomatosis, hepatotoxicity, an ichthyosislike dermatosis, aplastic anemia, and dyspnea.^{37–39,53,85,115,133}

Hemolytic and aplastic anemias are reported, as well as methemoglobinemia, following acute paradichlorobenzene ingestion.^{25,52,53,110}

Paradichlorobenzene is classified by IARC as a Group 2B, possibly carcinogenic to humans, based upon evidence of carcinogenicity from experimental animal studies. In mice and rats, chronic exposure was associated with the development of both hepatocellular carcinomas and adenomas in male and female mice, and renal tubular cell adenocarcinomas and mononuclear-cell leukemias developed in male mice.^{5,6,17,87,88,136} Evidence for carcinogenicity in humans from paradichlorobenzene exposure is limited. One case series reported five cases of leukemia that may have been associated with paradichlorobenzene exposure.^{88,135} No additional epidemiologic data on human carcinogenesis from paradichlorobenzene exposure is available.

Diagnostic Testing

Both paradichlorobenzene and its primary metabolite, 2,5-dichlorophenol, can be identified in blood and urine following exposure.¹⁵ Identification of 2,5-dichlorophenol can confirm exposure to paradichlorobenzene. Quantifying the amount of paradichlorobenzene in the urine of workers may be useful for monitoring occupational exposures.⁴¹ Qualitative or quantitative testing for paradichlorobenzene or its metabolites is not generally indicated when managing a patient with an acute overdose. Structural CNS abnormalities, including toxic leukoencephalopathy, may be noted on imaging studies such as MRI.¹⁴

Management

Most unintentional exposures to paradichlorobenzene do not cause life-threatening toxicity. Asymptomatic patients with unintentional exposures can be managed as outpatients. Patients who should be evaluated in a health care facility include those with clinical signs or symptoms, suicidal patients, and patients who have had a large exposure.

Gastrointestinal decontamination has not been studied in patients who ingest paradichlorobenzene. Most patients with unintentional exposures do not require gastrointestinal decontamination. However, administration of activated charcoal, 1 g/kg, although not studied, is reasonable for patients with large, intentional ingestions. If present, GI symptoms such as nausea and vomiting should be managed with supportive care, including hydration and antiemetics. Laboratory testing is generally not helpful in the acute setting unless there is clinical evidence for hemolysis or methemoglobinemia. Transfusion of packed red blood cells should be considered for hemolysis and anemia. Methylene blue should be considered for symptomatic methemoglobinemia.

Asymptomatic patients should be referred for follow-up evaluation in 24 to 48 hours postexposure as development of hemolysis or methemoglobinemia may be delayed. Careful discharge instruction should be provided to patients should they become symptomatic.

MOTH REPELLENT RECOGNITION

Health care providers occasionally must determine whether a mothball is made of naphthalene, paradichlorobenzene, or camphor since management and prognosis for each chemical is different. When the container is unavailable, as is often the case, mothballs are difficult to distinguish based on appearance, odor, texture, or size. Most mothballs are white, crystalline, and have a noxious odor.¹³⁴ Camphor moth repellents are more oily than both naphthalene and paradichlorobenzene mothballs. If controls are available, moth repellents can often be differentiated based on their odor and texture.⁸ Although most new paradichlorobenzene moth repellents are slightly larger than most new naphthalene moth repellents, all moth repellents shrink over time when exposed to air, making size an unreliable differentiating characteristic. Identifying a moth repellent as paradichlorobenzene can often permit outpatient management, saving both hospital resources and unnecessary concern. The tests described in [Table 105–1](#) and shown in [Fig. 105–2](#) might allow rapid identification of the component of an unknown moth repellent. When performing these tests, it is most helpful to have camphor, naphthalene, and paradichlorobenzene controls available for comparison.

TABLE 105–1. Moth Repellents: Laboratory Differentiation

Characteristic	Camphor	Naphthalene	Paradichlorobenzene
Water solubility (g/L)	1.2	0.03	0.08
Buoyancy in water	Floats	Sinks	Sinks
Buoyancy in water saturated with table salt	Floats	Floats	Sinks
Radiopacity	Radiolucent	Faintly radiopaque	Densely radiopaque
Melting point	350.6°F (177°C)	176°F (80°C)	127.4°F (53°C)
Placement in covered test tube in 140°F (60°C) water bath	Does not melt	Does not melt	Melts
Boiling point	399.2°F (204°C)	424.4°F (218°C)	345.2°F (174°C)
Addition of chloroform	Untested	Blue color	No reaction
Place on copper wire in a flame	Untested	Flame is yellow-orange	Initially flame is yellow-orange then bright green
Solubility in turpentine	Untested	Fast	Slow

FIGURE 105–2. Radiograph of mothballs. Paradichlorobenzene (→) is densely radiopaque, whereas naphthalene (→) is faintly radiopaque.

SUMMARY

- Paradichlorobenzene has largely replaced both camphor and naphthalene in the United States, but exposures to all three compounds occur, especially in immigrant communities.
- It is reasonable to consider activated charcoal administration in patients with large ingestions if no contraindication is present, such as CNS depression, active vomiting, or seizures.
- Seizures are commonly observed after camphor ingestion, and deaths are reported due to status epilepticus. Camphor induced seizures are responsive to benzodiazepines, propofol, and barbiturates.
- Hemolytic anemia and methemoglobinemia can be observed after naphthalene and, less frequently, paradichlorobenzene exposures. Appropriate supportive care, packed red blood cell transfusions, and methylene blue administration should be considered for symptomatic patients.
- Simple tests such as radiography and buoyance tests may help identify the unknown mothball.

HISTORY AND EPIDEMIOLOGY

As early as 1927, legislation in the United States governing the packaging of lye-and acid-containing products mandated that warning labels be placed on these products. In response to the recognition that caustic exposures were more frequent in children, the Federal Hazardous Substances Act and Poison Prevention Packaging Act were passed in 1970; these acts mandated that all caustics with a concentration greater than 10% be sold in child resistant containers. By 1973, the household concentration for child-resistant packaging was lowered to 2%. In addition, the subsequent development of poison prevention education dramatically decreased the incidence of unintentional caustic injuries in children in the United States. The positive impact of both regulatory legislation and public health intervention is evident when observing the decreasing number of significant exposures in the United States⁴⁹ compared to the number of exposures in developing nations that lack these policies.

In the United States, even though legislation limiting the concentration of caustics has existed since the early 20th century, exposures to both acids and alkalis continue to be significant. Data collected by the American Association of Poison Control Centers from 2007 through 2010 revealed 29,748 acid exposures and 13,800 alkali exposures. Of these, 4273 (14.4%) acid exposures and 2645 (19.2%) alkali exposures resulted in moderate to major outcomes and a total of 25 deaths occurred (Chap. 136).

In children, exposures usually consist of household products and occur in an unsupervised setting. In adults, exposures to household or industrial products may result from occupational exposure, suicide attempts, and assaults. Exposure to caustics may occur via the dermal, ocular, respiratory, and gastrointestinal routes.

Caustics cause diverse histologic and functional damage on contact with tissues depending on the tissue and caustic involved. Table 106–1 lists common caustics and the commercial products that contain them. Many are available for home use, in both solid and liquid forms, with variations in viscosity, concentration, and pH.

TABLE 106–1. Sources of Common Caustics

<i>Xenobiotic</i>	<i>Applications</i>
Acetic acid	Permanent wave neutralizers, photographic stop bath
Ammonia (ammonium hydroxide)	Toilet bowl cleaners, metal cleaners and polishes, hair dyes and tints, antirust products, jewelry cleaners, floor strippers, glass cleaners, wax removers
Benzalkonium chloride	Detergents
Boric acid	Roach powders, water softeners, germicide
Formaldehyde, formic acid	Deodorizing tablets, plastic menders, fumigant, embalming agent
Hydrochloric acid (muriatic acid)	Metal and toilet bowl cleaners
Hydrofluoric acid	Antirust products, glass etching, microchip etching
Iodine	Antiseptics
Mercuric chloride (HgCl ₂)	Preservative
Methylethyl ketone peroxide	Industrial synthetic agent
Oxalic acid	Disinfectants, household bleach, metal polish, antirust products, furniture refinisher
Phenol (creosol, creosote)	Antiseptics, preservatives
Phosphoric acid	Toilet bowl cleaners
Phosphorus	Matches, fireworks, rodenticides, methamphetamine synthesis
Potassium permanganate	Illicit abortifacient, antiseptic solution
Selenious acid	Gun bluing agent
Sodium hydroxide	Detergents, paint removers, drain cleaners and openers, oven cleaners
Sodium borates, carbonates, phosphates, and silicates	Detergents, electric dishwasher preparations, water softeners
Sodium hypochlorite	Bleaches, cleansers
Sulfuric acid	Automobile batteries, drain cleaners
Zinc chloride	Soldering flux

Morbidity and mortality from exposures to caustics is a worldwide problem. One study from India that described outcomes in patients with acid ingestions found that acute complications occurred in 39.1% of cases and death in 12.2%.¹⁰⁶

Although less frequent, intentional exposures by adults are invariably more significant. One study noted that while children comprised 39% of admissions for caustic ingestions, adults comprised 81% of patients requiring treatment.³⁶ The severity of a caustic injury may not be immediately evident in patients who present shortly after exposure. Predicting which patients will require immediate interventions to prevent morbidity and mortality requires the determination and evaluation of multiple clinical and laboratory parameters. This chapter reviews the pathophysiology and approach to patients with potentially serious exposures.

PATHOPHYSIOLOGY

A caustic is a xenobiotic that causes both functional and histologic damage on contact with tissue surfaces. Although there are many ways to categorize caustics, they are most typically classified as acids or alkalis. An acid is a proton donator and causes significant injury, generally at a pH below 3. An alkali is a proton acceptor and causes significant injury, generally at a pH above 11. [Chapter 12](#) contains a more detailed discussion of the chemistry of acids and bases. The extent of injury is modulated by duration of contact; ability of the caustic to penetrate tissues; volume, pH, and concentration; the presence or absence of food in the stomach; and a property known as titratable acid/alkaline reserve (TAR). TAR quantifies the amount of neutralization needed to bring the pH of a caustic to that of physiologic tissues. Neutralization of caustics takes place at the expense of the tissues, resulting in the release of thermal energy, producing burns. Generally, as the TAR of a caustic increases, so does the ability to produce tissue damage.^{5,40} Some xenobiotics, such as zinc chloride and phenol, have a high TAR and are capable of producing severe burns even though their pH is near physiologic.

Alkalis

Following exposure to an alkaline xenobiotic, dissociated hydroxide (OH^-) ions penetrate tissue surfaces, producing a histologic pattern of liquefactive necrosis ([Figs. 106–1 and 106–2](#)). This process includes protein dissolution, collagen destruction, fat saponification, cell membrane emulsification, transmural thrombosis, and cell death.⁵ Animal studies following alkali exposure to the eye³⁹ demonstrate rapid formation of corneal epithelial defects with eventual deep penetration that may lead to perforation. Similarly, animal studies of the esophagus demonstrate that erythema and edema of the mucosa occur within seconds followed by an inflammatory reaction extending to the submucosa and muscular layers. The alkali, such as sodium hydroxide (“liquid lye”), then continues to penetrate until the OH^- concentration is sufficiently neutralized by the tissues.^{5,53}

FIGURE 106–2. Endoscopy images of a 20 year-old man following ingestion of sodium hydroxide. (A) Grade IIa

noncircumferential burn of the midesophagus. **(B)** Grade IIb circumferential burn of the distal esophagus. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Although federal regulations have lowered the maximal available household concentration of many caustics, two industrial strength products seem to be readily available and therefore warrant special mention: ammonium hydroxide and sodium hypochlorite. Ammonia (ammonium hydroxide) products are weak bases—partially dissociated in water—that can cause significant esophageal burns, depending on the concentration and volume ingested.³⁶ Household ammonium hydroxide ranges in concentration from 3% to 10%. Strictures have formed in patients who ingested 28% solutions.⁷² Sodium hypochlorite is the major component in most industrial and household bleaches. Severe injuries typically only occur in patients with large-volume ingestions of concentrated products and most other patients do well with supportive care.^{13,36} A series of 393 patients with household bleach ingestions demonstrated no stricture formation.⁵² Likewise, a canine model found that although vomiting was commonly associated with bleach ingestion, no esophageal lesions were noted, and perforation occurred only following prolonged contact.⁵²

Ingestion of button batteries were once considered a unique caustic exposure. Composed of metal salts and a variety of alkaline xenobiotics, such as sodium and potassium hydroxide, leakage of battery contents was a legitimate concern. In recent years, however, new techniques used in the production of button batteries that effectively prevent leakage have shifted the concern following their ingestion from caustic to foreign body exposure with the potential for electrical injury. For a more in-depth review of the management of button battery ingestion, the reader is referred to the previous editions of this text and one recent study that describes the electrical injuries that follow ingestion of large-diameter lithium cells lodged in the esophagus for longer than 2 hours.⁵⁴

Household detergents, such as laundry powders, laundry pods,⁸⁹ and dishwasher detergents, contain silicates, carbonates, and phosphates, and have the potential to induce caustic burns and strictures, even when ingested unintentionally.¹⁴ Airway compromise also may occur,^{14,21,60} but the majority of exposures result in only minor toxicity.

Cationic detergents include quinolinium compounds, pyridinium compounds, and quaternary ammonium salts. These are frequently found in products for industrial use, as well as household fabric softeners. A concentration greater than 7.5% can cause severe burns.⁵⁸

Acids

In contrast to alkaline exposures, following exposure to an acid, hydrogen (H^+) ions desiccate epithelial cells, producing an eschar and resulting in a histologic pattern of coagulation necrosis. This process leads to edema, erythema, mucosal sloughing, ulceration, and necrosis of tissues. Dissociated anions of the acid (Cl^- , SO_4^{2-} , PO_4^{3-}) also act as reducing agents, further injuring tissue.

Ophthalmic exposure to acids results in coagulative necrosis that tends to prevent further penetration into deeper layers of the eye.

In most series, following an acid ingestion, both the gastric and esophageal mucosa are equally affected.^{19,106} On occasion, the esophagus may be spared damage while severe injury is noted in the stomach^{27,36} (Fig. 106–3). This result tends to be a rarer finding than concomitant injury to both stomach and esophagus and is probably related to the rapid transit time of liquid acids through the upper gastrointestinal tract. Skip lesions from acid ingestions may be a function of viscosity and contact time.³⁶ Additionally, acid-induced pylorospasm may lead to gastric outlet obstruction, antral pooling, and perforation.^{19,105} A cat model of the effects of sulfuric acid on the esophagus revealed a coagulative necrosis of the mucosa with whitish discoloration of the tissues and underlying smooth muscle spasm.⁵ Other animal models demonstrate esophageal motility dysfunction and shortening.^{92,93}

FIGURE 106–3. Postmortem specimen from a man with an intentional ingestion of a mixture of phosphoric and hydrochloric acid that was used as a brick cleaner. Note the relative sparing of the esophagus in contrast to full-thickness injury with perforation of the stomach. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Chapters 98 and 107 contain a more detailed discussion of mercury and hydrofluoric acid, respectively, each a unique caustic, and the management specific to their exposure.

Classification and Progression of Caustic Injury

Esophageal burns, secondary to both alkali and acid exposures, are classified based on endoscopic visualization that employs a grading system similar to that used with burns of the skin. Grade I burns are generally defined by hyperemia or edema of the mucosa without evidence of ulcer formation.^{17,105} Grade II burns include submucosal lesions, ulcerations, and exudates. Some authors further divide grade II lesions into grade IIa, noncircumferential lesions, and grade IIb, near-circumferential injuries.¹³ Grade III burns are defined as deep ulcers and necrosis into the periesophageal tissues (Table 106–2).^{26,30}

TABLE 106–2. Evaluation of Caustic Injuries and Management

<i>Grading of Caustic Injury by Endoscopic Visualization</i>	<i>Associated Tissue Findings</i>	<i>Likelihood of Stricture Formation</i>	<i>Suggested Nutritional Support</i>	<i>Indication for Antibiotics, Steroids</i>	<i>Indication for Stenting</i>
I	Hyperemia or edema of mucosa without ulcer formation	None	Resume diet as tolerated	None	None
IIa	Submucosal lesions, ulcers, exudates that are noncircumferential	Low	Soft diet as tolerated or tube feeds (following nasogastric tube placement under direct visualization)	No indication for steroids; antibiotics only with identified source of infection	None
IIb	Submucosal lesions, ulcers, exudates that are near-circumferential	High	Due to risk of perforation, feeding via gastrostomy, jejunostomy, or total parenteral nutrition should be instituted as rapidly as possible	No indication for steroids; antibiotics only with identified source of infection	Consider intraluminal stents, nasogastric tubes to prevent strictures
III	Deep ulcers and necrosis into periesophageal tissues	High	Due to risk of perforation, feeding via gastrostomy, jejunostomy, or total parenteral nutrition should be instituted as rapidly as possible	No indication for steroids; antibiotics only with identified source of infection	Consider intraluminal stents, nasogastric tubes to prevent strictures

Human case reports, postmortem studies, histologic inspection of surgical specimens, and experimental animal models

reveal a consistent pattern of injury and repair following caustic injury.⁸⁶ As wound healing of gastrointestinal tract tissue occurs, neovascularization and fibroblast proliferation take place, laying down new collagen and replacing the damaged tissue with granulation tissue. A similar pattern of repair occurs following caustic injuries of the eye.

Burns of the esophagus may persist for up to 8 weeks as remodeling takes place and may be followed by esophageal shortening. If the initial injury penetrates deeply enough, there is progressive narrowing of the esophageal lumen. The dense scar formation presents clinically as a stricture. Strictures can evolve over a period of weeks to months, leading to dysphagia and significant nutritional deficits. Grade I burns carry no risk of stricture formation.^{17,105} Grade II circumferential burns lead to stricture formation in approximately 75% of cases. Grade III burns invariably progress to stricture formation and are also at a high risk of perforation.^{3,36}

CLINICAL MANIFESTATIONS

The gastrointestinal tract, respiratory tract, eyes, and skin of a patient can be sites of caustic injury. Caustics may produce severe pain on contact with any of these tissues. By far, the majority of long-term morbidity and mortality from caustic exposure results from ingestion.

In general, patients who have ingested either alkalis or acids have similar initial presentations. Depending on the type, amount, and formulation (solid vs. liquid) as well as the percent of tissue exposed, ingestion may lead to the development of severe pain of the lips, mouth, throat, chest, or abdomen. Oropharyngeal edema and burns may lead to drooling and rapid airway compromise. Symptoms of esophageal involvement include dysphagia and odynophagia, whereas epigastric pain and hematemesis may be symptoms of gastric involvement.

Respiratory tract damage may occur through direct inhalation or aspiration of vomitus, leading to the clinical manifestations of hoarseness, stridor, and respiratory distress. Injury may result in epiglottitis, laryngeal edema and ulceration, pneumonitis, and impaired gas exchange. Patients may also be tachypneic or hyperpneic as a compensatory response to the metabolic acidosis, with elevated lactate concentrations from necrotic tissue or hemodynamic compromise.

Predictors of Injury

Many attempts have been made to define a method for clinical identification of patients with grade II or III esophageal injuries as these injuries typically progress to severe complications. Various studies, mostly involving alkaline xenobiotics, examine the predictive value of stridor, oropharyngeal burns, drooling, vomiting, and abdominal pain. A retrospective study of 378 children admitted for a caustic injury found that signs or symptoms could not be used to predict significant esophageal injury.²⁶ However, one prospective study of 79 children evaluated for vomiting, drooling, and stridor found that a combination of two or more of these signs were predictive of significant esophageal injury as visualized on endoscopy.¹⁷ Another study found that drooling, buccal mucosal burns, and white blood cell count were significant independent predictors of severe gastrointestinal tract injury following acid ingestions.³⁵ Studies evaluating the presence or absence of oropharyngeal burns as a predictor of distal esophagogastric injury have repeatedly found this finding to be poorly predictive.^{1,17,26,30,80,99} In one study esophageal injury was present 51.5% of the time in the absence of oropharyngeal lesions, and 22.2% of these were second- and third-degree burns.⁸⁰ A prospective study of alkali ingestions in both adults and children found that stridor was 100% specific for significant esophageal injury, but this was based on only three patients with this sign.³⁰

Based on these findings, endoscopy, a standard diagnostic tool used in the management of caustic ingestions, is recommended in all patients with intentional ingestions. Endoscopy should also be performed in any patient with an unintentional ingestion in the presence of stridor and in any patient with two or more of the following findings: pain, vomiting, and drooling.^{17,82} Children with unintentional caustic ingestions who remain completely asymptomatic and tolerate liquids after a few hours of observation probably require no further medical care.

The abdominal examination is likewise an unreliable indicator of the severity of injury. The presence of abdominal pain suggests tissue injury, but the absence of pain or findings on abdominal examination does not preclude life-threatening gastrointestinal damage.^{22,104} Esophageal perforations result in mediastinitis and are commonly associated with fever, dyspnea, chest pain, and subcutaneous emphysema of the neck and chest. Although indicative of viscus perforation, abdominal peritoneal signs are late findings.

In addition to the direct effects that occur with tissue contact, systemic absorption of acids may result in damage to the spleen, liver, biliary tract, pancreas, and kidneys. This may also produce a metabolic acidosis, hemolysis, and, ultimately, death.⁴²

Significant complications can occur at various stages of wound recovery. Most importantly, these include airway compromise, hemodynamic instability secondary to hemorrhage from vascular erosion or septic shock, perforations of the gastrointestinal tract with the development of mediastinitis or peritonitis, and other overwhelming infections from bacteria residing in the oropharynx. A patient who survives acute injury with an acid or an alkali may also subsequently develop

stricture formation, gastric atony, decreased acid secretion, pseudodiverticula, and gastric outlet obstruction.^{29,105}

Other complications include dysmotility of the pharynx and esophagus,¹⁸ formation of aorto-and trachea-esophageal fistulas, delayed massive hemorrhage from erosion into a great vessel, and pulmonary thrombosis.^{9,36,70,91} Those patients surviving a few weeks after a grade II or III injury may subsequently present with dysphagia and vomiting from stricture formation. Injury involving the entire length of the esophagus as well as hematemesis and increased serum lactic dehydrogenase were useful indicators for the development of strictures in one study.⁷³ Strictures may also present with esophageal motility disorders caused by impaired smooth muscle reactivity. The early assessment and long-term prognosis may be better defined by manometric studies of the esophagus, which provide precise information about the severity of the initial injury and aid in long-term prognosis.²⁸

Long-term survivors of moderate and severe injury of the esophagus have a risk of esophageal carcinoma that is estimated to be 1000 times higher than that of the general population and appears to present with a latency of up to 40 years.⁴

DIAGNOSTIC TESTING

Laboratory

All patients with presumed serious caustic ingestion should have an evaluation of serum pH, blood type and cross-match, complete blood count, coagulation parameters, electrolytes, and urinalysis. Elevated prothrombin time (PT) and elevated partial thromboplastin time (PTT),¹⁰⁴ as well as an arterial pH lower than 7.22,¹¹ are associated with severe caustic injury.

Absorption of nonionized acid from the stomach mucosa may result in acidemia. Following ingestion of hydrochloric acid, hydrogen and chloride ions (both of which are accounted for in the measurement of the anion gap) dissociate in the serum resulting in a hyperchloremic normal anion gap metabolic acidosis. Other acids, such as sulfuric acid, result in an elevated anion gap metabolic acidosis because the sulfate anion (SO_4^{2-}) is not measured in the calculation of the anion gap. Although alkalis are not absorbed systemically, necrosis of tissue may result in a metabolic acidosis with an elevated lactate concentration.

A gastric pH greater than 7.30 correlated retrospectively with severe alkaline injury. The prospective usefulness of this information is limited, as obtaining gastric secretions without direct visualization is dangerous. One prospective study in children also found an increase in uric acid and decreases in phosphate and alkaline phosphatase concentrations to be useful in predicting the presence of esophageal injuries.⁷⁵

Radiology

Chest and abdominal radiographs are useful in the initial stages of assessment to detect gross signs of esophageal or gastric perforation. Signs of alimentary tract perforation that may be present on plain radiographs include pneumomediastinum, pneumoperitoneum, and pleural effusion. However, these studies have a limited sensitivity, and an absence of findings does not preclude perforation.¹⁰⁴ Free intraperitoneal air is best visualized on an upright chest radiograph. Occasionally, free air may only be visible on the lateral view. In patients too ill to obtain an upright chest radiograph, an abdominal radiograph obtained with the patient in a left-side-down position may reveal free intraperitoneal air adjacent to the liver. Additionally, bedside ultrasound may be useful in the diagnosis of free air and is based entirely on the lack of visualization of the usual intraperitoneal structures.^{10,71} Computed tomography (CT) scanning is considerably more sensitive than both radiography and ultrasound for detecting viscus perforation and should be obtained in patients with potentially serious caustic ingestions as soon as is feasible.^{23,101}

A contrast esophagram is useful for defining the extent of esophageal injury (Fig. 106–4). Late after the ingestion, it can detect stricture formation. In patients for whom there is a high suspicion for esophageal perforation and in whom adequate visualization of the upper gastrointestinal tract by endoscopy is not possible (grade IIb circumferential burns or grade III burns), an enteric contrast study (esophagram and upper gastrointestinal series) can be obtained 24 hours after the ingestion.⁸¹ Extravasation of contrast outside of the gastrointestinal tract is diagnostic of perforation.¹⁰⁵ Water-soluble contrast should be used when perforation is suspected as it is less irritating than barium contrast agents to mediastinal and peritoneal tissues if extravasated. However, barium contrast agents are more radiopaque than water-soluble agents and offer greater radiographic detail. Consequently, some authors recommend barium swallow if the water-soluble contrast study is nondiagnostic but demonstrates no leak.^{32,57,94} In addition, if there is risk of aspiration, barium is preferred because water-soluble contrast material can cause a severe chemical pneumonitis. Significant necrosis with impending perforation may be suspected on enteric contrast studies when there is esophageal dilation, displacement of the pleural reflection, and widening of the pleuroesophageal line. Enteric contrast studies may fail to detect perforation and therefore must be interpreted within the context of the patient's clinical status.^{9,15,34}

FIGURE 106-4. (A) Barium swallow several days after ingestion of liquid lye shows the esophagus to be atonic. There is poor coating of the esophagus, suggesting edema and intramural penetration. Note that the initial evaluation immediately following a caustic ingestion to assess the extent of injury is esophagoscopy, rather than a contrast esophagram. (B) Four months later, a repeat barium esophagram shows a severe stricture below the middle third of the esophagus. The barium barely passes the stricture, and the remainder of the esophagus is pencil thin. (Used with permission of Emil J. Balthazar, MD, Professor of Radiology, New York University.)

The role for CT scans in caustic ingestions has not been prospectively investigated. In the acute stage, CT has great sensitivity at detecting extraluminal air in the mediastinum or peritoneal cavity as a sign of perforation. In addition, CT can visualize the esophagus and stomach distal to severe caustic burns that cannot be safely seen using endoscopy or an esophagram. CT may therefore replace enteric contrast radiography for detection of perforation within 24 hours of a caustic ingestion. Additionally, one retrospective study suggests that CT grading of esophageal injuries may be superior to endoscopy for prediction of the degree of esophageal damage and the development of stricture formation. These results suggest a promising future role for this noninvasive study following caustic ingestions.⁸⁸ Other imaging modalities have been proposed for assessing esophageal injury after ingestion of caustic substances, including technetium 99m-labeled sucalfate swallow for the presence of injury⁶⁶ and esophageal ultrasonography for determining the depth of injury.⁶⁹

Another use of radiographic imaging is to noninvasively follow the patient after initial evaluation and stabilization. For example, contrast radiography is routinely used in the weeks or months following a caustic ingestion to detect esophageal narrowing representing stricture formation.⁹⁶ Chest CT may also be useful to determine the response of strictures to dilation procedures.

Endoscopy

Endoscopy should be performed within 12 hours and generally not later than 24 hours postingestion. Numerous case series demonstrate that the procedure is safe during this period. Early endoscopy serves multiple purposes in that it allows patients with minimal or no evidence of gastrointestinal injury to be discharged. It also offers a rapid means of obtaining

diagnostic and prognostic information while shortening the period of time that patients forego nutritional support, permitting more precise treatment regimens.^{13,22,36,56,65,82,90,100,105} The use of endoscopic assessment from the second or third day postingestion is discouraged and should be avoided between 5 days and 2 weeks postingestion; at this time, wound strength is least and the risk of perforation is greatest.

The choice of rigid versus flexible endoscopy is dependent on the comfort and experience of the endoscopist. The flexible endoscope has a smaller diameter but may require gentle insufflation of air to achieve or enhance visualization. A prospective evaluation of the role of fiberoptic endoscopy in the management of caustic ingestions recommended the following guidelines: (a) direct visualization of the esophagus prior to advancing the instrument, (b) minimal insufflation of air, (c) passage into the stomach unless there is a severe (particularly circumferential) esophageal burn, and (d) avoidance of retroversion or retroflexion of the instrument within the esophagus. Provided that the patient is hemodynamically stable and endoscopy is indicated, every attempt should be made to visualize the esophagus, stomach, and duodenum as soon as possible after a caustic ingestion.¹⁰⁵ The absence of burns in the esophagus does not imply that severe necrosis and ulcerations do not exist in the stomach^{65,99,105} and duodenum. In the case of termination of endoscopy because of grade IIb or grade III esophageal burns, barium studies,⁸² CT scan, or consideration of surgical exploration should be undertaken to visualize remaining structures.

Endoscopy permits limited evaluation of gastrointestinal injury. For example, the endoscopist is able to appreciate only the mucosal surface of tissues, not the serosal side. This is especially evident in stomach ulcerations, which may appear black and necrotic from a true burn through the layers of the stomach or from the effect of stomach acid on the blood exposed from a shallow lesion. As mentioned above, in these cases, endoscopic ultrasonography during endoscopy may improve assessment of injury depth.^{7,52} Often, however, only direct visualization of serosal and mucosal tissues with laparoscopy or laparotomy allows for definitive evaluation.

Most cases of perforation clearly linked to endoscopy have occurred when the endoscope was advanced through an esophagus with severe circumferential lesions—a violation of current endoscopic standards.¹⁰⁰ In addition, perforations are also more likely to occur when rigid instruments are used in children or in uncooperative patients. Thus the use of the flexible endoscope and adequate procedural sedation has decreased the complications from endoscopic evaluation.⁸² Some authors advocate the presence of a surgeon during endoscopy to assist in the assessment for potential surgical intervention.

MANAGEMENT

Acute Management

As in the case of any patient presenting with a toxicologic emergency, the health care provider must adhere to universal precautions utilizing early decontamination as described in the following section. Initial stabilization should include airway inspection and protection, basic resuscitation principles, and decontamination. Examination of the oropharynx for signs of injury, drooling, and vomitus, as well as careful auscultation of the neck and chest for stridor, may reveal signs of airway edema that should prompt immediate airway protection. Careful and constant attention to signs and symptoms of respiratory distress and airway edema, such as a change in voice, are essential and should prompt early intubation as airway edema may rapidly progress over minutes to hours.

If airway involvement is significant enough to warrant intubation, it is best to mobilize a team of the most skilled physicians early in case of unforeseen complications. A delay in prophylactic airway protection may make subsequent attempts at intubation or bag-valve-mask ventilation difficult or impossible. Direct visual inspection of the vocal cords with a fiberoptic laryngoscope may also reveal signs of impending airway compromise. Patients necessitating intubation are best served by direct visualization of the airway either via direct laryngoscopy or fiberoptic endoscopy, as perforation of edematous tissues of the pharynx and larynx is a grave complication that may occur during blind nasotracheal intubation attempts. Neuromuscular blockers should be avoided for induction of intubation as airway edema and bleeding may distort the anatomy limiting the ability to successfully ventilate via bag-valve-mask should intubation be unsuccessful.

Nonsurgical airway placement is recommended whenever possible as both cricothyrotomy and tracheostomy may interfere with the surgical field if esophageal repair is required.¹⁰⁴ Some patients with significant ingestions, however, may require emergent surgical airway intervention. The decision to perform a surgical airway is dependent on the status of the patient, the ability to orotracheally or nasotracheally intubate via a fiberoptic endoscope, and the comfort of the physician performing the procedure.

Following control of the airway, large-bore intravenous access should be secured and volume resuscitation initiated. Although not studied, most clinicians agree that patients with signs of caustic-induced airway edema benefit from dexamethasone 10 mg (intravenous) in adults and 0.6 mg/kg up to a total dose of 10 mg in children. Both acid and alkali ingestions cause “third spacing” of intravascular fluid to the interstitial space, which can result in hypotension. Empiric rehydration with clinical assessment of central venous pressures should be used to guide individual fluid requirements. Serial physical examinations and constant monitoring of the vital signs and urine output may provide information on the severity of the exposure and the progression in clinical status.

Decontamination, Dilution, and Neutralization

Decontamination should begin with careful, copious irrigation of the patient's skin and eyes when indicated to remove any residual caustic and to prevent contamination of other patients, staff, and equipment.

Gastrointestinal decontamination is usually limited in patients with a caustic ingestion. Induced emesis is contraindicated, as it may cause reintroduction of the caustic to the upper gastrointestinal tract and airway. Activated charcoal is also contraindicated, as it will interfere with tissue evaluation by endoscopy and preclude a subsequent management plan. Additionally, most caustics are not adsorbed to activated charcoal.

Exceptions, such as cationic detergents, that do bind well to activated charcoal⁵⁷ have not been evaluated with a large series. For this reason, therapy with activated charcoal following any caustic ingestion cannot be recommended. Gastric emptying via cautious placement of a narrow nasogastric tube with gentle suction may be attempted to remove the remaining acid in the stomach only in patients with large, life-threatening, intentional ingestions of acid who present within 30 minutes. Although this technique has never been studied and carries the risk of perforation, the outcome for this particular group of patients with massive exposure is often grave, and options for treatment are limited. Therefore, preventing absorption of some portion of the ingested acid may have potential benefit in reducing systemic toxicity. Although the procedure has the potential to induce injury, a risk-to-benefit analysis favors gastric emptying following a presumed lethal ingestion.

In contrast, gastric emptying should be avoided with alkaline and unknown caustic ingestions as blind passage of a nasogastric tube carries the risk of perforation of damaged tissues, a risk that outweighs the benefit.

Exceptions to the general rules of gastrointestinal decontamination of caustics exist in the management of zinc chloride (ZnCl_2) and mercuric chloride (HgCl_2).^{49,95} Both are caustics with severe systemic toxicity.^{12,62,63,79} Ingestion of these xenobiotics causes life-threatening illness from cationic metal exposure. The local caustic effects, though of great concern, are less consequential than the manifestations of systemic absorption. Therefore, prevention of systemic absorption should be addressed primarily, followed by the direct assessment and management of the local effects of these xenobiotics. Initial management to prevent systemic absorption includes aggressive decontamination with gentle nasogastric tube aspiration and administration of activated charcoal. In vitro data exist to suggest adequate activated charcoal adsorption of Hg^{2+} .²

The use of dilutional therapy has been examined using in vitro, ex vivo, and in vivo models in an attempt to assess its efficacy in caustic ingestions. An early in vitro model demonstrated a dramatic increase in temperature when either water or milk was added to a lye containing crystal drain opener (NaOH).⁸⁷ Another in vitro model found less consequential increases in temperature despite large volumes of diluent. Results of both studies suggested that dilutional therapy was of limited benefit.⁶¹ Dilutional therapy was also attended by an increase in temperature in an ex vivo study of harvested rat esophagi that examined the histopathologic effects of saline dilution after an alkali injury. Additionally, the usefulness of dilution appeared to be inversely related to the length of time from exposure, with minimal efficacy when delay to initiation was as short as 30 minutes.^{42,43} In contrast, an in vivo canine model of alkaline injury demonstrated that water dilution did not cause an increase in either temperature or intraluminal pressures.⁴⁵

The extrapolation of these variable results to humans with caustic ingestions is limited and suggests that histologic damage can only be attenuated by milk or water when administered within the first seconds to minutes following ingestion.^{5,42-45,53} For solid, as opposed to liquid, substances (eg, crystal lye), there may be some value for delayed dilutional therapy, as tissue contact time is increased with solids and their concentration is usually 100% over a small surface area. Milk may be the best diluent to attenuate the heat generated by a caustic.

Caution should be used in advising patients or family members about the use of diluents. A child who refuses to swallow or take oral liquids should never be forced to do so. In general, dilutional therapy should be limited to the first few minutes after ingestion in patients who have no airway compromise; are not complaining of significant pharyngeal, chest, or abdominal pain; are not vomiting; and are alert. Dilutional therapy should be avoided in patients with nausea, drooling, stridor, or abdominal distension as it may stimulate vomiting and result in reintroduction of the caustic into the upper gastrointestinal tract.⁸⁷

Attempts at neutralization of ingested caustics should likewise be avoided. This technique has the potential to worsen tissue damage by forming gas and generating an exothermic reaction. In vitro and ex vivo models demonstrate that neutralization of caustics generates heat, requires a large volume to attain physiologic pH, and may have limited usefulness in preventing histologic damage if delayed beyond the first several minutes following caustic exposure.^{41,87} In one in vivo canine model, orange juice was used to neutralize sodium hydroxide-induced gastric injury and demonstrated no change in temperature or intraluminal pressure.⁴⁵ Despite this study, neutralization is not recommended; there are no other data demonstrating that clinical outcome is improved.

Surgical Management

The decision to perform surgery in patients with caustic ingestions is obvious in the presence of either endoscopic or diagnostic imaging evidence of perforation,¹⁰⁴ severe abdominal rigidity, or persistent hypotension. Hypotension is a grave

finding and often indicates perforation or significant blood loss. Additionally, elevated PT and PTT,¹⁰⁴ as well as acidemia,¹¹ are correlated with severe caustic injury.

Many patients will not have an obvious indication for surgical intervention despite impending perforation, necrosis, sepsis, or delayed hemorrhage. Although more challenging to diagnose, all these sequelae are potentially avoidable if surgery is performed early⁷⁴ as morbidity and mortality increase in patients whose surgery is delayed.^{22,47,85} For this reason, some surgeons advocate surgery for all patients with grades II and III esophageal burns identified on endoscopy.^{22,65} This aggressive approach allows for direct inspection of serosal surfaces and an opportunity for early surgical repair.

Multiple studies have attempted to codify the signs and symptoms necessary or sufficient to rapidly identify patients who would benefit from surgery but who lack clear clinical indications. Several retrospective and prospective series of caustic ingestions found that patients with large ingestions (>150 mL), shock, acidemia, or coagulation disorders tended to have severe findings on surgical exploration. These studies also reinforce that the abdominal examination was frequently unreliable in predicting the need for surgery.^{104,106} It should be noted, again, that patients with severe acid injuries may lack abdominal pain, abdominal tenderness, and have positive findings on diagnostic imaging.^{19,106} One author used a stepwise approach of bronchoscopy, endoscopy, and abdominal ultrasonography to provide additional information regarding extent of injury prior to surgery. Respiratory distress, ascites, pleural fluid, and a serum pH less than 7.2 were used as indications for surgery.¹⁰⁴ A history of a large-volume caustic ingestion (between 40 and 200 mL) should also prompt consideration of early surgical intervention as delay is associated with increased mortality.^{19,104}

Surgical intervention may include laparotomy for tissue visualization, resection, and repair of perforations. Laparoscopy may also be used, although it may not allow inspection of the posterior aspect of the stomach.

Subacute Management

The extent of tissue injury dictates the subsequent management and disposition of patients with caustic ingestions.

Grade I Esophageal Injuries. Patients with isolated grade I injuries of the esophagus do not develop strictures and are not at increased risk of carcinoma. Their diet can be resumed as tolerated. No further therapy is required. These patients can be discharged from the emergency department as long as they are able to eat and drink and their psychiatric status is stable.

Grade IIa Esophageal Injuries. If endoscopy reveals grade IIa lesions of the esophagus and sparing of the stomach, a soft diet can be resumed as tolerated or a nasogastric tube can be passed under direct visualization. If oral intake is contraindicated because of the risk of perforation, feeding via gastrostomy, jejunostomy, or total parenteral nutrition should be instituted as rapidly as possible. Providing interim enteral support is imperative as metabolic demands are increased in any patient with a significant burn.

Grades IIb and III Esophageal Injuries. Patients with grades IIb and III lesions must be followed for the complications of perforation, infection, and stricture development. Strictures are a debilitating complication of both acid and alkali ingestions that can evolve over a period of weeks or months. Strictures form as a result of the natural process by which the body repairs injured tissue through the production of collagen with resultant scar formation. Although corticosteroid therapy is theorized to arrest the process of inflammatory repair and potentially prevent stricture formation, there is some evidence that grade III burns, in particular, will progress to stricture formation regardless of therapy.^{3,36,100} In addition to stricture formation, patients with grade III burns are also at high risk for other complications, including fistula formation, infection, and perforation with associated mediastinitis and peritonitis. The use of corticosteroids in the management of grade III burns may mask infection and make the friable, necrotic esophageal tissue more prone to perforation.⁷⁸ For these reasons, corticosteroid therapy is not a recommended therapy for grade III esophageal burns. When required in these patients for other indications such as caustic-induced airway inflammation, short-term corticosteroids should be administered.

Currently, some controversy exists regarding the use of corticosteroid therapy in the management of grade IIb circumferential esophageal burns. A meta-analysis of studies completed from 1956 to 1991, with a total of 361 patients, evaluated the efficacy of corticosteroid therapy and found that in patients with grades II and III esophageal burns, strictures formed in 19% of the corticosteroid-treated group and in 41% of the untreated group.⁴⁶ The usefulness of the results of this study, however, are limited as no distinction was made between grades II and III burns. Another meta-analysis of studies from 1991 to 2003, with a total of 211 patients, was unable to find a benefit in treating patients with corticosteroids with grades II and III esophageal burns.⁷⁸ However, no distinction was made between grades II and III burns. A systematic pooled analysis of studies from 1956 to 2006, with a total of 328 patients, attempted to reevaluate the usefulness of corticosteroid therapy in grade II esophageal burns. Although methodologically limited, this study found no benefit in treating patients with steroids with grade II esophageal burns. A major limitation to the clinical usefulness of this study is that no distinction was made between grades IIa and IIb burns.²⁴ In addition, a multitude of case series also failed to clearly differentiate between grades IIa, IIb, and III lesions, making clinical application of their results difficult.^{3,15,68,100}

Two prospective studies attempted to evaluate the efficacy of corticosteroid therapy for caustic injuries to the esophagus. Both these studies failed to show a benefit of corticosteroid therapy, and one even suggested harm.^{2,3,49} It is imperative that the clinician understands that neither study clearly differentiates between grades IIb and III lesions.

Adequate human data demonstrating the efficacy of corticosteroids with or without antibiotics in the treatment of grade IIb circumferential lesions have yet to be generated. Because of the inherent risks involved in this therapy and the paucity of data supporting their use, corticosteroid therapy in the management of grade IIb esophageal burns can no longer be routinely recommended.

No major outcome studies have investigated the use of antibiotics alone as prophylactic treatment for stricture prevention, but most clinicians would agree that it is probably best to reserve antibiotics for an identified source of infection.

A variety of other management strategies have been used in an attempt to prevent strictures and esophageal obstruction. In both animal models⁸⁴ and in human case series,^{38,67,83} intraluminal stents and nasogastric tubes⁶⁷ made of silicone rubber tubing can successfully maintain the patency of the esophageal lumen. For nutritional support, the stents are usually attached to a feeding tube secured in the nasopharynx through which the patient can receive feedings without interfering with esophageal repair. These tubes are left in place for 3 weeks^{83,84} and are often used with concomitant corticosteroid and antibiotic therapy. In animal models, the use of a stent for 3 weeks is superior in maintaining esophageal patency when compared to corticosteroids and antibiotics alone.⁸⁴

Potential disadvantages of esophageal stents include mechanical trauma at the site and increased reflux, both of which may inhibit healing.⁹³ A feline model of esophageal exposure to sodium hydroxide used stents but reported deaths from aspiration and mediastinitis.⁸⁴ One series of 251 humans exposed to caustics who were managed with silicone rubber stents found that the procedure was successful in preventing stricture formation.⁸

Additionally, a plethora of animal models have attempted to identify therapies that attenuate oxidative damage, inhibit synthesis, or stimulate breakdown of collagen and thereby prevent stricture formation. β -Amino propionitrile,⁵⁹ penicillamine,²⁷ N-acetylcysteine,⁵⁵ halofuginone,^{31,77} vitamin E, sphingosylphosphorylcholine, colchicine, erythropoietin,⁶ mitomycin C,⁹⁸ ozone,³³ fibroblast growth factor,⁷⁶ 5-fluorouracil,²⁰ ibuprofen,³⁷ and retinoic acid¹⁶ are some of these xenobiotics. As none of these treatments have been adequately studied in humans, they cannot currently be recommended in the routine management of caustic ingestions.

Chronic Treatment of Strictures

Commonly, the management of esophageal strictures includes early endoscopic dilation, for which a variety of types of dilators are available. Contrast CT can be used to determine maximal esophageal wall thickness, which can then be used to predict response, as well as the number of sessions required to achieve adequate dilation. Multiple dilations are often necessary. In one study, patients with a maximal esophageal wall thickness of 9 mm or greater required more than seven sessions to achieve adequate dilation. This was significantly higher than in patients with a lesser maximal wall thickness. Measurement of maximal wall thickness may be also be useful in determining long-term follow-up, type of nutritional support, and the potential need for surgical repair as an alternative to dilations. It may also provide an indication for those who should undergo dilation under fluoroscopy to limit the risk of perforation.

The risk of perforation from esophageal dilation is decreased if the initial procedure is delayed beyond 4 weeks postingestion, when healing, remodeling, and potential stricture formation in the esophagus have already taken place. Several series report perforation secondary to esophageal dilation.^{36,81,100} Following perforation, patients may complain of dyspnea or chest pain with associated subcutaneous emphysema or pneumomediastinum. Diagnostic imaging may identify the perforation and provide information for emergent surgical repair if the diagnosis is unclear.

Patients with stricture formation require long-term endoscopic follow-up for the presence of neoplastic changes of the esophagus that may occur with a delay of several decades.⁶

Management of Ophthalmic Exposures

Ophthalmic exposures frequently occur from splash injuries and malicious events as well as from the alkaline byproducts of sodium azide released in automobile air bag deployment and rupture.¹⁰² The mainstay of therapy for these patients is immediate irrigation of the eye for a minimum of 15 minutes with 0.9% sodium chloride, lactated Ringer solution, or tap water, if it is the only therapy immediately available. Several liters of irrigation fluid are recommended. The normal pH of ophthalmic secretions is approximately 6.5 to 7.6. This can be tested colorimetrically by using a urine dipstick, which can test a range of pH from 5 to 9.⁶⁴ Litmus paper can be used in the same fashion. Another useful option in acid exposures is Nitrazine paper, which changes color from yellow to dark blue at a pH above 6.5.²⁵ These different test strips can be applied to the ophthalmic secretions to test the baseline pH and followed with intermittent evaluations after 15 minutes of lavage to determine the adequacy of irrigation. If these xenobiotics are not readily available, irrigation should not be

delayed, as the depth of penetration of the caustic agent will determine outcome. Anterior chamber irrigation may be required and should be performed emergently by an ophthalmologist. A thorough eye examination should be completed, and follow-up should be arranged. [Chapter 25](#) contains a more detailed description of the evaluation and management of toxicologic emergencies of the eye.

SUMMARY

- Initial management of all patients with caustic exposures begins with universal precautions in an effort to prevent further contamination of staff, other patients, and equipment.
- In patients with caustic ingestions, airway assessment and stabilization are of primary importance. Airway edema is the only indication for initiation of corticosteroid therapy.
- There is no routine recommendation for induced emesis, lavage, activated charcoal, neutralization, or dilutional therapy.
- Significant caustic injury should be suspected in all patients with intentional ingestions and in patients with unintentional ingestions presenting with stridor; vomiting; drooling; and pain in the oropharynx, chest, or abdomen.
- All patients with suspected significant ingestions should undergo endoscopy or CT emergently so that effective treatment strategies may be initiated expeditiously.
- Surgeons should be involved in the initial assessment of all patients with suspected significant ingestions and those who have an acute abdomen or hypotension so that any surgical intervention deemed necessary may be performed promptly.

107 HYDROFLUORIC ACID AND FLUORIDES

Mark Su

HISTORY AND EPIDEMIOLOGY

Hydrofluoric acid (HF) has been known for centuries for its ability to dissolve silica. The Nuremberg artist Schwanhard is given credit for the first attempt to use HF vapors to etch glass in 1670.⁴⁷ Today, HF has multiple applications and is widely used throughout industry. In addition to glass etching, HF is used in brick cleaning, etching microchips in the semiconductor industry, electroplating, leather tanning, rust removal, and the cleaning of porcelain.⁴⁷ From 2009 to 2011, the American Association of Poison Control Centers reported more than 1000 exposures to HF and at least 3 deaths (Chap. 136). The hands are the commonest part of the body injured. Exposures to HF often occur as an unintentional occupational hazard. The actual number of work-related poisonings from HF appears difficult to quantitate because of limitations in International Classification of Diseases (ICD) medical coding and the lack of notification of regional poison centers by worksites.¹⁰

HF is also the commonest cause of fluoride poisoning, although other forms of fluoride, including sodium fluoride (NaF), ammonium bifluoride (NH_4HF_2), and sodium or zinc fluorosilicate, may also produce significant toxicity. Historically, NaF has been used as an insecticide, rodenticide, an antihelminthic for swine, and a delousing powder for poultry and cattle. NH_4HF_2 is mainly used in industrial inorganic chemistry, especially in the processing of alloys and in glass etching. Other fluoride salts are widely used in the steel industry, drinking water, toothpaste additives, electroplating, lumber treatment, and the glass and enamel industries.

The widespread use of HF and fluoride containing compounds has resulted in significant toxicity. In 1988, an oil refinery in Texas released a cloud of hydrogen fluoride gas that resulted in 36 people requiring hospital treatment.³⁸ The petroleum industry has since been plagued by similar HF incidents.⁹⁸ NaF was responsible for the poisoning of 263 people and 47 fatalities when it was mistaken for powdered milk and unintentionally combined with scrambled eggs.⁵⁵ Following ingestion, fluoride salts can be converted to HF in vivo, resulting in significant fluoride toxicity.

CHEMISTRY

HF is synthesized as the product of gaseous sulfuric acid and calcium fluoride, which is subsequently cooled to a liquid.⁵⁷ Aqueous HF is a weak acid, with a pK_a of approximately 3.2; as such, it is approximately 1000 times less dissociated than an equimolar strong acid such as hydrochloric acid. HF is generally available in concentrations from 3% to 40%, for use in both industry and the home. Anhydrous HF is highly concentrated (>70%) and used almost exclusively for industrial purposes. HF has unique properties that can cause life-threatening complications following seemingly trivial exposure.

Sodium fluoride is commonly synthesized by the reaction of sodium hydroxide (NaOH) with HF, with subsequent purification by recrystallization. NaF is highly soluble in water and readily dissociates.⁴

To synthesize NH_4HF_2 , ammonium fluoride (NH_4F) is first formed by the reaction of ammonium hydroxide (NH_4OH) and HF. Ammonium fluoride is then converted to bifluoride by dehydrating the aqueous solution.

Fluorine is the most electronegative element in the Periodic Table due to the relatively large number of protons in the nucleus compared to molecular size and the minimal amount of screening or shielding by inner electrons. Other halides possess lesser electronegative properties. Consequently, the corresponding anion of fluorine, the fluoride ion (F^-), is a weak base because it possesses a limited ability to donate its electrons. Liberation of the fluoride ion from the previously mentioned compounds is believed to be the major determinant of toxicity.

PATHOPHYSIOLOGY

Exposures to HF occur via dermal, ocular, inhalation, oral and rectal routes.¹⁸ A permeability coefficient of 1.4×10^{-4} cm/sec allows HF to penetrate deeply into tissues prior to dissociating into hydrogen ions and highly electronegative fluoride ions.³⁴ These fluoride ions avidly bind to extracellular and intracellular stores of calcium and magnesium,

depleting them, and ultimately leading to cellular dysfunction and cell death.^{11,54,63} The alteration in local calcium homeostasis causes neuroexcitation and accounts for the development of neuropathic pain. Furthermore, ischemia related to calcium dysregulation mediated localized vasospasm is likely an additional contributory factor to the development of pain.^{42,89}

Formation of insoluble calcium fluoride (CaF_2) is proposed as the etiology for both the precipitous fall in serum calcium concentration and the severe pain associated with tissue toxicity. There are several theories regarding the actual fate of calcium and fluoride ions in tissues. In vitro evidence suggests that fluorapatite is formed in the presence of phosphate and hydroxyapatite. This may be a more likely pathway for disposition of the fluoride ion.¹¹ Fluorapatite, like calcium fluoride, is insoluble and its formation may contribute to the clinical findings recognized following HF toxicity.

Fluoride also binds magnesium and manganese and there is in vitro evidence that this interferes with many enzyme systems. In the anhydrous form, the high concentration of hydrogen ions in HF also produces a caustic burn similar to that caused by strong acids (**Chap. 106**). The minimal lethal oral dose in humans is approximately 5 to 10 g of sodium fluoride.⁵

CLINICAL MANIFESTATIONS

Local Effects

Skin. The extent of tissue injury following dermal exposure is determined by the volume, concentration, and contact time with the tissues. Following dermal exposure, the concentration of HF is directly related to the onset of pain at the contact site.^{31,56,88} High concentrations (greater than 50%) cause immediate pain with visible tissue damage.⁸² Exposure to household rust-removal products (6% and 12% HF) is often associated with a delay of several hours before pain develops.^{31,83,93,94} The initial site of injury may also appear relatively benign despite significant subjective complaints of pain. Over time, the tissue may become hyperemic, with subsequent blanching and coagulative necrosis. As calcium complexes precipitate, a white discoloration of the affected area may appear.⁷³ (**Fig. 107–1**) The development of ulceration is dependent on the concentration and duration of contact.^{27,48,56} If more than 2% of the body surface area is burned with highly concentrated HF, life-threatening systemic toxicity should be expected.^{20,70,72,82,88} Small body surface area exposures to low concentrations typically do not result in life-threatening systemic toxicity, although fatalities have resulted with dermal exposures to concentrated HF covering less than 5% body surface area.⁸⁷

FIGURE 107–1. Severe injury to the fingers resulted from exposure to hydrofluoric acid. Note the arterial line in place for administration of calcium. (Used with permission of The New York City Poison Center Toxicology Fellowship Program.)

Pulmonary. Patients with inhalational exposures can present with a variety of signs and symptoms depending on the HF concentration and exposure time. Thirteen oil refinery workers exposed to a low-concentration HF mist experienced minor upper respiratory tract irritation.⁵² In contrast, in a mass inhalational exposure to HF, throat burning, and shortness of breath were among the more common chief complaints.⁹⁸ Some of these patients developed hypoxemia and hypocalcemia, and they had altered pulmonary function tests. Stridor, wheezing, rhonchi, and erythema and ulcers of the upper respiratory tract were described. Eye pain was also noted, reinforcing the fact that ocular injury typically accompanies inhalational or dermal exposures.^{52,61,77,98}

Gastrointestinal. Intentional ingestion of concentrated HF (or other fluoride salts) causes significant gastritis yet often

spares the remainder of the gastrointestinal tract. Patients promptly develop vomiting and abdominal pain. Although systemic absorption is rapid and almost invariably fatal, there is at least one report of a patient who ingested a low concentration (8%) of HF and suffered multiple episodes of ventricular fibrillation but was successfully resuscitated⁸⁵ Following HF ingestion, patients may present with an altered mental status, airway compromise, and dysrhythmias^{13,55,58,85}

Ocular. HF results in more extensive injury to the eye than most other acids⁶⁴ Ocular exposures from liquid splashes or hydrogen fluoride gas can rapidly denude the corneal and conjunctival epithelium, leading to stromal corneal edema, conjunctival ischemia, sloughing, and chemosis⁴⁷ Fluoride ions can penetrate deeply to affect the anterior chamber structures⁴⁷ The effects are usually noted within one day⁴⁷ Other possible findings include corneal revascularization, recurrent epithelial erosions, and, sometimes, keratoconjunctivitis sicca (dry eye) developing as a long-term complication with subsequent corneal ulcers^{7,64,78}

Systemic Effects

Significant systemic toxicity can occur via any route of exposure because of the ability of HF to penetrate tissues. The potential for systemic toxicity is an important consideration in management as patients should be rapidly decontaminated and treated.^{12,16,33,81,82,90,91} Fatal exposures to HF by any route share the similar features of hypocalcemia, hypomagnesemia, and, in many cases, hyperkalemia as preterminal events.^{4,13,19,23,33,56,58,65,66,88} In some circumstances, the hypocalcemia severely disrupts the coagulation cascade, resulting in the inability of blood clotting, even on postmortem examination.^{58,68,69}

Fatalities from HF may occur as a result of either sudden onset myocardial conduction failure or ventricular fibrillation. Although the evidence regarding the mechanism of myocardial irritability is inconclusive, electrolyte disturbances that lead to ventricular dysrhythmias, including ventricular fibrillation, are thought to be the primary cause of death in patients with severe systemic fluoride poisoning.^{20,71,82,88,102} Although one postmortem human case reveals significant structural myocardial injury,⁶² interestingly, histologic abnormalities of the myocardium do not occur in canine models.^{25,68}

Systemic fluoride toxicity results in hypocalcemia, by mechanisms not fully elucidated. In addition, fluoride may cause calcium ions to accumulate intracellularly, leading to an efflux of potassium ions into the extracellular space.^{25,54,68} One in vitro study performed with human erythrocytes suggests that fluoride inhibition of $\text{Na}^+\text{-K}^+\text{-ATPase}$ and $\text{Na}^+\text{-Ca}^{2+}$ exchange lead to intracellular hypercalcemia.⁶⁷ The subsequent hyperkalemia may alter the automaticity and resting potential of the heart, leading to fatal dysrhythmias⁶⁵ (Chap. 64). Dogs treated with quinidine, a potassium efflux blocker, are protected from lethal doses of intravenous sodium fluoride.²⁵ Likewise, amiodarone, which also blocks potassium efflux, has demonstrable efficacy in both in vitro and in vivo models of fluoride toxicity.⁸⁶ However, efficacy in humans has not been studied or documented. Furthermore, the mechanism of toxicity may be much more complicated.¹⁰⁴ A child with systemic fluoride toxicity, who was appropriately repleted with calcium, and had normal electrolytes still experienced nonfatal ventricular fibrillation.^{12,104} Perhaps this is because serum potassium, calcium, and magnesium concentrations only partly represent tissue concentrations.^{11,12,25,65,66} Furthermore, HF may directly impair myocardial function. Rabbits exposed to topical HF over 2% of their total body surface area developed focal necrosis of myocardial fibers, as well as significant elevations in cardiac enzymes that persisted for almost 5 days after injury.¹⁰³

Assessing Severity of Clinical Exposures

Historical and clinical features of an exposure will determine which HF exposures are life threatening. All oral and inhalational exposures should be considered potentially fatal, as should burns of the face and neck, regardless of HF concentration. Inhalational exposure should be assumed for all patients with skin burns of greater than 5% body surface area, any exposure to HF concentrations greater than 50%, and head and neck burns.⁴⁶ Patients presenting with altered mental status directly related to HF are critically ill and necessitate rapid therapy.

HF concentrations of greater than 20% have the potential for significant toxicity in any patient, even if only a small surface area is exposed.⁶⁰ As a general rule, patients who experience severe pain within minutes of contact are most likely exposed to a very high concentration of HF, and their condition can rapidly deteriorate. An otherwise well appearing patient may have a precipitous demise without any clinical manifestations of hypocalcemia. Furthermore, it is possible that systemic toxicity may occur following a seemingly trivial exposure. A 36 year-old man was exposed to 20% HF over 3% of his body surface area and subsequently developed hypocalcemia, hypomagnesemia, and cardiac arrest 16 hours later.¹⁰⁰

DIAGNOSTIC TESTING

Diagnostic testing for systemic fluoride poisoning is currently based on monitoring of serum electrolytes. Ionized calcium, magnesium, and potassium should be serially monitored.³³ Additional information may be obtained from a venous or

arterial blood gas analysis. As systemic toxicity progresses, a metabolic acidosis will likely develop.¹¹ Serum fluoride concentrations may be assessed but the results will not return in a clinically relevant timeframe. Although a serum fluoride concentration of 0.3 mg/dL has been reported as fatal, one patient survived with a serum fluoride concentration of 1.4 mg/dL.^{88,104}

Electrocardiographic (ECG) findings of both hypocalcemia (prolonged QT interval) and hyperkalemia (peaked T waves) may be reliable indicators of toxicity (Chap. 16).^{4,16,33,36,41,69,88} In fact, ECG findings of peaked T waves from hyperkalemia have preceded the onset of ventricular dysrhythmias in reported cases, thus potentially serving as a marker of severe fluoride toxicity.^{12,66} It should be noted that in some cases of HF poisoning, hypokalemia is reported^{26,32,100} and for unclear reasons, may be specifically related to sodium fluoride toxicity.⁹⁵

MANAGEMENT

General

For patients with more than localized exposure to low concentration HF or any exposure to high concentration HF, the mainstay of management is to prevent or limit systemic absorption, assess for systemic toxicity, and rapidly correct any electrolyte imbalances. Intravenous access should be secured. An ECG should be obtained and examined for dysrhythmias and signs of hypocalcemia, hypomagnesemia, and hyperkalemia. The patient should be attached to continuous cardiac monitoring and have a rapid assessment of serum electrolyte concentrations. A Foley catheter should be placed as indicated to follow urine output if the patient cannot void.

Rapid airway assessment and protection should occur early in patients with inhalation or ingestion, respiratory distress, vomiting, or burns significant enough to cause a change in mental status or voice.

For patients with less significant dermal exposures, recent studies have focused on alternatives to irrigation with water or saline as topical decontamination techniques. The compound “hexafluorine” is promoted for dermal and ocular decontamination of HF splashes.^{59,84} Hexafluorine is a proprietary name whose chemical formula is not disclosed, and papers that report success have strong ties to the manufacturer. In a controlled and blinded experimental study, hexafluorine treatment was less effective than irrigation with water followed by the application of topical calcium.⁴⁰ In a follow-up animal study, water irrigation was as effective as hexafluorine in preventing systemic toxicity from HF.⁴³ At this time, until further objective data are available, the use of hexafluorine for initial decontamination of HF exposures is not indicated.

An iodine containing preparation was evaluated in a guinea pig model of HF-induced burns and found to be associated with significant reductions in ulceration area.⁹⁹ Iodine is hypothesized to inhibit apoptosis and has demonstrated protective effects against burns from various alkylating agents, including mustard gas.⁹⁹ Unfortunately, because experience with iodine treatment of human HF burns is lacking, it cannot be recommended at this time.

The most important therapy for skin exposures is rapid removal of clothing and irrigation of the affected area with copious amounts of water or saline, whichever is more readily available.^{2,51,53,57}

One report describes a woman who was dying from severe HF toxicity who was treated by amputation of the affected limb and survived. Although rarely considered, this may be an alternative measure for patients who are critically ill and demonstrate an inadequate response to all other therapeutic modalities.^{15,49}

Dermal Toxicity

Several therapeutic options are studied and described in animal models for treatment of topical HF burns. Unfortunately, many study designs use histologic or subjective wound inspection as outcome parameters,^{17,74} some with unblinded inspection.^{14,29,49,51,71} These animal models do not address the clinically important parameters of pain reduction, cosmesis, and functionality.

Topical calcium gel should be applied to the affected area (Antidotes in Depth: A29). A commercial gel is available in the United States, but an acceptable substitute may be created, if necessary. This is accomplished by mixing 3.5 g of calcium gluconate powder in 150 mL of sterile water-soluble lubricant, or 25 mL of 10% calcium gluconate in 75 mL of sterile water-soluble lubricant.^{2,17,46} If calcium gluconate is unavailable, calcium chloride or calcium carbonate can be used in a similar formulation.²¹ This topical therapy for severe and non-life-threatening exposures scavenges fluoride ions. An animal study examining the efficacy and mechanism of topical calcium gel therapy found that the fluoride ion concentration in the calcium gel was significantly higher than non calcium-containing gel controls. Although this was a limited study, these animals also had a decrease in urinary fluoride ion concentration as compared to controls, suggesting less overall tissue absorption of the HF.⁵¹ Delivery of calcium transcutaneously may be enhanced by various means. In a rodent study of HF burns, iontophoretic (facilitated transport using an electromotive force) delivery of calcium ions appeared to increase calcium concentrations in vitro and improve pathologic changes in vivo.¹⁰¹ Significant limitations to this study are timing to administration of therapy and feasibility in patients with complex burns.⁷⁹ Human data are lacking.

Dimethyl sulfoxide (DMSO) mixed with topical calcium salts may also facilitate the transport of calcium ions through the skin to penetrate deeply into the tissues. DMSO also is able to act as a scavenger of free radicals, thus limiting inflammation and ongoing injury.³⁶ Although one group of authors recently advocated the combined use of DMSO and calcium,³⁶ concerns remain over reported adverse effects of DMSO.⁴⁷ There are currently inadequate data to support the use of DMSO in the treatment of HF burns.

Four therapies have had variable success in human exposures; the application of calcium via topical, intradermal, intravenous, and intraarterial routes. After irrigation, a gel solution of calcium carbonate or gluconate can be applied directly to the affected area or mixed directly into a sterile surgical glove and then placed on the burned hand for 30 minutes. Two case series report limited success with this therapy.^{2,21} Some patients describe prompt and dramatic relief of pain. Alternatively or simultaneously, analgesics can be administered orally or parenterally as needed but preferably not to the point of sedation, because local pain response will guide therapy. Digital nerve blocks with subcutaneous lidocaine or bupivacaine can be used for patients presenting 12 to 24 hours after the injury from a low concentration of HF and with no systemic signs of toxicity, at which time topical calcium salts are unlikely to be effective.²⁸

If topical gel therapy fails within the first few minutes of application, consideration should be given to intradermal therapy with dilute calcium gluconate, because the benefit of topical gel in pain control often occurs immediately. This treatment may have limited usefulness, however, in nondistensible spaces such as fingertips. Histologic studies in animal models demonstrate that 10% calcium chloride solution can be damaging to the tissues and is contraindicated.^{28,35} The preferred method is to approach the wound from a distal point of injury and inject intradermally no more than 0.5 mL/cm² of 5% calcium gluconate. Although one author recommends a palmar fasciotomy whenever this method of treatment is used in the hand,² this practice is not currently recommended unless a compartment syndrome is present. The potential for iatrogenic injury exceeds the potential benefit of injections in the hand. The limits of intradermal injection include the potential to increase soft tissue damage without adequate relief, infection, and inadequate space to safely inject without causing a compartment syndrome.

Effective pain relief is especially problematic for nail bed involvement, leading some authors to suggest removal of the nail. This approach has some advantages in accessing the affected area. However, it is a painful procedure that is often cosmetically undesirable and the outcome is not always significantly improved.

If the wound is large or on a section of the fingerpad or an area that is not amenable to intradermal injections, consideration should be given to the use of intraarterial calcium gluconate. This procedure delivers calcium directly to the affected tissue from a proximal artery. Placement should be ipsilateral and proximal to the affected area, usually in the radial or brachial artery. The method of obtaining access is somewhat debated. Because of the potential to damage the endothelial lining of the artery and because extravasation can have potentially devastating consequences, angiographic confirmation or direct visualization of the vessel was formerly recommended. This practice is still prudent if cannulation of the artery is expected to be difficult because of prior surgery or if an anatomic deformity is suspected. If the arterial line is carefully placed in a single attempt, and a good confirmatory arterial wave form is obtained, the infusion can be started. The recommended protocol consists of 10 mL of 10% calcium gluconate added to either 40 mL of D₅W (dextrose 5% in water) or 0.9% sodium chloride solution infused continuously over 4 hours.^{1,2,75,83,92,93} This results in a 2% calcium gluconate solution. An animal model examined the effect of undiluted 10% calcium gluconate intraaortically. Although the model did not involve exposure to HF, there was significant tissue injury in the vessel wall as compared to a 2% calcium gluconate solution.²⁸ Calcium chloride has also been used successfully, although the potential for vessel injury and extravasation are significant and there is no defined benefit over calcium gluconate.^{92,105} The complications associated with the use of intraarterial calcium infusion in several case series were relatively benign and included radial artery spasm, hematoma, inflammation at the puncture site, and a fall in serum magnesium.^{80,93} After the infusion is initiated, patients typically experience significant pain relief. Patients requiring an arterial line for treatment should be admitted to the hospital, as the majority will require more than one treatment, and some patients may require as many as five separate infusions of calcium gluconate. Although wounds may require Debridement,² some suggest that following intraarterial calcium infusion, tissue can be salvaged that initially would not have been considered viable.⁹⁴ There are no reported cases of clinically significant hypercalcemia following infusion as the total dose infused is quite low, although serum calcium concentrations were not always routinely recorded.

Magnesium salts are an alternative or adjunctive therapy to the administration of calcium salts for patients with dermal HF burns. Magnesium hydroxide and magnesium gluconate gel show histologic evidence of efficacy in rabbit models of dermal HF burns.¹⁷ Two other animal models of intravenous magnesium for dermal HF burns also suggest wound healing efficacy.^{24,97} Magnesium is suggested to be an antidote for fluoride poisoning because magnesium fluoride is more soluble than calcium fluoride and magnesium is readily excreted by the kidneys.⁹⁸ However, these magnesium models inadequately address the disadvantage of magnesium salt solubility, and both topical and intravenous magnesium therapy remain incompletely evaluated in humans and therefore not routinely recommended.

Another reported therapy for localized HF poisoning is an intravenous Bier block technique that uses 25 mL of 2.5%

calcium gluconate. In one case, the effects lasted 5 hours and there were no adverse events.³⁹ In two other cases of patients exposed to HF, a 6% calcium gluconate solution administered using this procedure resulted in rapid and complete analgesia with minimal tissue necrosis.⁸⁰ Although the intravenous Bier block technique is not reported as being used in a substantial number of patients, it may be particularly useful when intraarterial infusion is problematic.⁸⁰ Further data are required before this therapy is routinely recommended.

All patients with digital exposures to HF should be observed over 4 to 6 hours, as the pain is likely to recur and reapplication of the gel or an alternative therapy may be necessary. Even if successful pain control is achieved, the patient will require specialized follow-up and wound care.

Inhalational Toxicity

Patients with symptomatic inhalational injuries can be treated with nebulized calcium gluconate. A report of patients exposed to a low concentration of HF and treated with 4 mL of a 2.5% nebulized calcium gluconate solution demonstrated a subjective decrease in irritation with no adverse effects.⁵² Another report demonstrated a good outcome following nebulization of a 5% calcium gluconate solution in a patient with an inhalational exposure.⁵⁰ Because nebulized calcium gluconate appears to be a relatively benign therapy, a dilute solution should be given to all patients with symptomatic inhalational exposures to any concentration of HF.³⁰

Ingestions

In patients with intentional ingestions of HF, gastrointestinal decontamination poses a dilemma. Induction of emesis is potentially harmful and not recommended. Although placement of a nasogastric tube to perform gastric lavage is clearly associated with risks to the patient, insertion of a nasogastric tube may be beneficial if done safely and in a timely manner. Consequently, gastric emptying via a nasogastric tube should be considered because these exposures are almost universally fatal.^{4,13,58,69} Health care providers should exercise extreme caution during this procedure because secondary dermal or inhalational exposures to the provider can occur in the absence of appropriate personal protection. If there is a possibility of inhalation by the provider, the area should be well ventilated. Acceptable forms of hand protection include gloves made of nitrile, butyl rubber, polyvinyl chloride, or neoprene. Latex gloves should not be used. Because aqueous HF is a weak acid, the risk of perforation by passage of a small nasogastric tube may be lower than the risk of death from systemic absorption.^{4,58} In the acidic environment of the stomach, more of the weak acid solution remains unionized, thus penetrating the gastric mucosa and causing rapid systemic poisoning. Moreover, activated charcoal is unlikely to adsorb the relatively small fluoride ions.

If an oral exposure occurs, a solution of calcium or magnesium salt should be delivered to the stomach as soon as possible to prevent HF penetration and to provide an alternative source of cations for the damaging electronegative fluoride ions.

When comparing the efficacy of calcium to magnesium salts, calcium may be better than magnesium in reducing the bioavailability of fluoride as described in a murine model.³⁸ Magnesium citrate in a standard cathartic dose, magnesium sulfate, or any of the calcium solutions can be administered orally to prevent absorption (Antidotes in Depth: A29). Although intuitive, evidence for the benefit of oral calcium or magnesium salts is limited. In a mouse model of oral HF toxicity, administration of calcium or magnesium containing solutions did not change average survival time.³⁷ The study results, however, were limited because the calcium and magnesium salts were premixed together with the HF during administration, thus being an inadequate model for the study of HF ingestion. In a more recent study, the survival rate of mice poisoned with NaF was significantly greater when treated with high doses of oral CaCl₂ or MgSO₄.⁴⁵

Ocular Toxicity

Patients with ocular exposures should have each eye irrigated with 1 L of 0.9% sodium chloride solution, lactated Ringer solution, or water.⁶⁴ Although there are limited data, repetitive or prolonged irrigation appears to worsen outcome.⁶⁴ A complete ophthalmic examination should be performed after the patient is deemed stable, and an ophthalmology consultation should be obtained (Chap. 25). One case report demonstrated a good outcome following ocular HF exposure with the use of 1% calcium gluconate eyedrops.⁷ Although two reviews also recommend the use of 1% calcium gluconate for this purpose,^{30,36} calcium salts tend to be irritating to the eye, and this therapy has not been adequately studied; consequently, use is not indicated at this time. There is no role for gel therapy or intraocular injection in these patients, because most calcium and magnesium salts are potentially toxic to ocular tissues and may actually worsen outcome.^{6,64}

Systemic Toxicity

If there is a clinical suspicion of severe toxicity, the immediate intravenous administration of both calcium and magnesium salts is recommended. In general, calcium gluconate is preferred over calcium chloride because of the risks associated with

extravasation (Antidotes in Depth: A29). Patients may require several grams of calcium to treat severe HF toxicity.³³ Intravenous magnesium can be administered to adults as 20 mL of a 20% solution (4 g) over 20 to 30 minutes. An approach that uses intravenous calcium or magnesium, and local calcium or magnesium gels, to limit absorption may protect against life threatening hypocalcemia and hyperkalemia. Due to the numerous adverse effects of systemic fluoride poisoning, administration of calcium and magnesium salts alone may be insufficient in improving survival from systemic fluoride poisoning.²² Furthermore, an animal model of hydrogen fluoride toxicity found that maintaining a normal acid–base balance was protective against HF toxicity.⁹⁶ Moreover, in a study of patients receiving enflurane anesthesia, urine alkalinization improved the excretion of fluoride.⁷⁶ Thus, it may be beneficial to correct any significant acidemia with hydration and intravenous sodium bicarbonate (calcium salts and sodium bicarbonate cannot be mixed). Since standard treatment for systemic fluoride toxicity includes administration of calcium salts and sodium bicarbonate, hyperkalemia is also addressed.

Treatment with large quantities of calcium and magnesium has not generally resulted in significant hypercalcemia or hypermagnesemia.³⁰ Several explanations are proposed. First, in systemically HF poisoned patients, total-body calcium and magnesium stores are severely decreased so that large doses are required for adequate repletion. Also, most patients who are exposed to HF are young and healthy, with normal kidney function.³⁰ Administration of calcium also results in antidiuretic hormone antagonism on renal tubular reabsorption resulting in polyuria, which facilitates the urinary excretion of calcium and magnesium.³⁰

Because most of the fluoride ions are eliminated renally,^{8,44,51,81} hemodialysis may be considered in patients with severe HF poisoning, particularly if kidney function is compromised. There are several reported cases of successful clearance of fluoride ions via hemodialysis with one case also using continuous venovenous hemodialysis.^{3,8,9} Furthermore, prolonged hemodialysis, beyond the standard 4-hour course, may be necessary in some cases.³ Because the reported clearance rate did not differ significantly from normally functioning kidneys, it is unclear whether hemodialysis alters outcome in patients with normal kidney function.

Although the use of quinidine, a potassium channel blocker, is protective in dogs,⁶⁸ it has not been studied or used in humans. At this time it cannot be routinely recommended but may be considered in the presence of life-threatening ventricular dysrhythmias.

SUMMARY

- Although HF has a pKa of approximately 3.2 and is considered a weak acid, it causes local and systemic toxicity because of fluoride binding to cations.
- Dermal exposure to HF causes severe pain, often before any physical manifestations are evident.
- Patients with greater than 2.5% body surface area HF burns should have serum calcium, magnesium, and potassium checked periodically. Admission may be required for prolonged electrolyte and cardiac monitoring.
- Therapy for local toxicity includes topical calcium salts and systemic analgesia. In some cases, intradermal or intraarterial administration of calcium may be required.
- Therapy for systemic toxicity includes all treatments for local toxicity plus intravenous calcium and magnesium salts, sodium bicarbonate, and potentially hemodialysis.

A29 ANTIDOTES IN DEPTH

Calcium

Mary Ann Howland

INTRODUCTION

Calcium is essential to maintain the normal function of the heart, vascular smooth muscle, skeletal system, and the nervous system. It is vital in enzymatic reactions, in neurohormonal transmission, and in the maintenance of cellular integrity.²¹ The endocrine system maintains calcium homeostasis. Approximately half of the total serum calcium is ionized and active, and the remainder is primarily bound to albumin. Hypercalcemia raises the threshold for nerve and muscle excitation, resulting in muscle weakness, lethargy, cardiac conduction disturbances, and coma.²¹ Hypocalcemia can result in hyperreflexia, muscle spasms, tetany, seizures, and QT interval prolongation (Chaps. 16 and 19).²¹

PHARMACOLOGY

Early evidence suggested that in hypocalcemic children,¹⁰ intravenous (IV) infusions of calcium chloride produce slightly larger increases in ionic calcium than infusions of calcium gluconate, but this concept has been challenged.^{43,70} Administration of equivalent molar doses of calcium found in calcium chloride (1 g CaCl₂ 10%) and calcium gluconate (3 g Ca gluconate 10%) produce similar serum ionized calcium concentrations, with both peaks occurring within 30 seconds in a model utilizing the anhepatic stage of liver transplant.⁴³ These results support the concept that simple dissociation of calcium from gluconate is responsible for releasing calcium, rather than hepatic metabolism.

ROLE IN CALCIUM CHANNEL BLOCKER TOXICITY

Calcium enters cells in numerous ways. In cardiac and smooth muscles the voltage-dependent L-type channels are inhibited by the calcium channel blockers (CCBs) available in the United States.^{5,60} Patients with CCB overdose (Chap. 61) may develop nausea, vomiting, hypotension, bradycardia, myocardial depression, sinus arrest, atrioventricular (AV) block, and metabolic acidosis with hyperglycemia, shock, pulmonary edema, altered mental status, and seizures.⁵⁰ Because CCBs do not alter either receptor-operated channels or the release of calcium from intracellular stores,⁶⁵ the serum calcium concentration remains normal in overdose.

IV administration of calcium to dogs poisoned with verapamil or diltiazem improves cardiac output secondary to increased inotropy.²⁵ The heart rate and cardiac conduction are affected minimally, if at all.^{22,25,56} Case reports and reviews of the literature suggest similar findings in humans.^{2,3,11,17,20,26,31,34,41,53,54,62}

Calcium should be administered to symptomatic patients with CCB overdoses.^{30,37,40} Unfortunately, the most seriously ill patients respond inadequately, and other measures are often required. The dose of calcium needed to treat patients with CCB overdose is unknown. In animal experiments, there appears to be a dose-related improvement.^{11,25} Since calcium chloride is extremely irritating to small vessels, subcutaneous tissue, and muscle, and may cause necrosis following extravasation, it is usually only administered through a central venous line. The customary approach is to administer an initial IV dose of 3 g of calcium gluconate (30 mL of 10% calcium gluconate) or 1 g of calcium chloride (10 mL of 10% calcium chloride) to adults.⁵⁰ Based on case reports, this dose may need to be repeated as clinically indicated. The hypothesis is that sufficient calcium must be present to compete with the CCB for binding to the L-type calcium channel. One author used a total of 10 g of calcium gluconate as 1 g boluses over 12 minutes after diltiazem induced asystole and another 2.5 g of calcium gluconate minutes later for a second asystolic event, with a resultant serum calcium concentration of 13.44 mg/dL (normal: 8.4–10.2 mg/dL) approximately 1 hour after administration of the calcium gluconate.³² Several authors have successfully treated patients with a total of 18 to 30 g of calcium gluconate or 13 g of calcium chloride over 2 to 12 hours, either by intermittent bolus dose or infusion, without apparent adverse effects.^{11,30,31,37,40,41} However, following the use of large doses of calcium, hypercalcemia can occur and is associated with severe consequences including

myocardial depression and intense vasoconstriction leading to multiorgan ischemia.⁶⁰ Introduction of hyperinsulinemia euglycemia (Antidotes in Depth: A17) and intravenous fat emulsion (Antidotes in Depth: A20) in the treatment of CCB overdose has diminished the need for extensive calcium administration. The provision of massive calcium doses should be limited, and if used, meticulous monitoring of ionized calcium is advised to avoid hypercalcemia (Table A29–1).

TABLE A29–1. Calcium Salts for Intravenous Use

	<i>Calcium Gluconate^a</i>	<i>Calcium Chloride (CaCl₂)^{a,b}</i>
10% Solution	10 mL = 1 g of Ca ²⁺ gluconate 10 mL = 4.5 mEq elemental Ca ²⁺	10 mL = 1 g of CaCl ₂ 10 mL = 13.6 mEq elemental Ca ²⁺
Adult dose	3 g (30 mL of 10% solution) over 10 minutes (unless in extremis—deliver over 30–60 seconds) Repeat every 10–20 minutes up to 3–4 doses as necessary	1 g (10 mL of 10% solution) over 10 minutes (unless in extremis—deliver over 30–60 seconds) Repeat every 10–20 minutes up to 3–4 doses as necessary
Pediatric dose (not to exceed the adult dose)	60 mg/kg (0.6 mL/kg) of 10% solution infused over 5–10 minutes (unless in extremis—deliver over 30–60 seconds) Repeat every 10–20 minutes up to 3–4 doses as necessary	20 mg/kg (0.2 mL/kg) infused over 5–10 minutes (unless in extremis—deliver over 30–60 seconds) Repeat every 10–20 minutes up to 3–4 doses as necessary

^aMonitor calcium after several doses and every 30 minutes during administration. ^bUse of a central venous line is recommended to avoid extravasation.

The administration of calcium to a patient with toxicity from cardioactive steroids such as digoxin might prove harmful.^{24,69} In the event of concurrent overdose with both a cardioactive steroid and a CCB, the early use of digoxin-specific antibody fragments (Antidotes in Depth: A19) should enable the subsequent safe use of calcium (Chap. 65).

Therapy in children is based on more limited data. The American Heart Association pediatric guidelines suggest an initial dose of 20 mg/kg of 10% calcium chloride (0.2 mL/kg), not to exceed the adult dose.¹ This is infused over 5 to 10 minutes, preferably into a central venous line. If a beneficial effect is observed, an infusion of 20 to 50 mg/kg/h follows. These guidelines preferentially suggest calcium chloride based on the study mentioned above that compared the chloride to the gluconate salt in critically ill children with hypocalcemia.¹⁰ However, since CaCl₂ may be irritating, calcium gluconate may be preferable, especially if central venous access is unavailable. The starting dose in children should be 60 mg/kg of 10% calcium gluconate (0.6 mL/kg), not to exceed the adult dose.

ROLE IN β -ADRENERGIC ANTAGONISTS TOXICITY

In vitro studies suggest that the negative inotropic action of β -adrenergic antagonists are related to interference with both the forward and reverse transport of calcium in the sarcoplasmic reticulum and the inhibition of microsomal and mitochondrial calcium uptake (Chap. 62).^{18,38,48} In a canine model of propranolol poisoning, the administration of calcium chloride improved mean arterial pressure, the change in maximal left ventricular pressure over time, and peripheral vascular resistance, but it had no significant effect on bradycardia or QRS complex prolongation.³⁹ Several case reports attest to the beneficial effects of IV calcium in β -adrenergic antagonist overdose.^{9,33,52,57} Because distinguishing an overdose of a CCB from that of a β -adrenergic antagonist may be difficult and the two may be taken simultaneously, a trial of IV calcium is appropriate for a presumed β -adrenergic antagonist overdose if cardioactive steroid toxicity can be excluded.

ROLE IN HYPOCALCEMIA SECONDARY TO ETHYLENE GLYCOL

Following ethylene glycol poisoning (Chap. 109) metabolism of the parent molecule generates oxalic acid, which complexes with calcium and subsequently precipitates in the kidneys, brain, and elsewhere, resulting in hypocalcemia.^{2,31,49,60,63} After exposure to ethylene glycol, the ionized calcium concentration should always be monitored, along with repeated examinations for signs of hypocalcemia such as QT interval prolongation, hyperreflexia, muscle spasms, tetany, and seizures (Chap. 19). IV calcium should be administered in the customary recommended doses (as above) to patients with these findings.

ROLE IN HYPOCALCEMIA SECONDARY TO HYDROFLUORIC ACID AND FLUORIDE-RELEASING XENOBIOTICS

Deaths from dermal, gastrointestinal, and pulmonary hydrofluoric acid (HF) exposures are well documented in the literature.^{13,23,68} In these cases, hypocalcemia is invariably present. Any body contact with HF (Chap. 107) can result in severe burns and death, depending on concentration, area exposed, and duration of exposure. The toxicity results from (a) release of free hydrogen ions; (b) complexation of fluoride with calcium and magnesium to form insoluble salts, which cause cellular necrosis; (c) liberation of potassium ions; and (d) cellular dehydration.^{12,19,42,44} Soluble salts of fluoride and bifluoride (eg, sodium, potassium, and ammonium) have all the toxicity associated with HF and should be managed accordingly. Following HF exposure, the gluconate salt of calcium is used topically and subcutaneously to manage minor to moderate cutaneous burns, intravenously to treat systemic hypocalcemia, and intraarterially to manage significant burns.^{2,12–14,16,19,23,42,44,47,51,55,58,66,67,72} Experimental studies demonstrate that when concentrated HF burns are immediately flushed with water and then treated with topical calcium, burn size is significantly reduced.⁸ Management of HF burns with a topical dimethyl sulfoxide (DMSO)–calcium gluconate combination seems promising, but a randomized clinical trial has yet to be published.²⁷ Although a DMSO preparation is not commercially available, a 2.5% calcium gluconate topical gel is marketed. In the event that the commercial preparation is inaccessible, a topical calcium gel can be prepared from calcium carbonate tablets, calcium gluconate powder or solution, and a water-soluble jelly such as K-Y Jelly (mix 3.5 g calcium gluconate powder or 35 mL of a 10% calcium gluconate solution or 10 g of calcium carbonate tablets or seven 500 mg crushed calcium gluconate tablets with 5 ounces of K-Y Jelly). An experimental study in rats demonstrated that iontophoretic delivery of calcium chloride appeared to enhance the delivery of calcium and to significantly reduce the burn area if applied within 30 minutes, and this may be a promising modality in the future.^{56,71}

The chloride salt is also acceptable for topical therapy. However, calcium chloride should never be injected into tissues (subcutaneously, intramuscularly), since severe tissue necrosis can result.

In patients with severe topical HF exposures, aggressive administration of regional IV calcium using a Bier block technique (10 mL of 10% calcium gluconate in a total volume of 40 mL) or intraarterial calcium (10 mL of 10% calcium gluconate in 50 mL (total volume) of 5% dextrose solution over 4 hours) may be required, along with frequent serum calcium determinations to titrate the dose.^{27,64} One patient who was massively exposed to HF required a total of 267 mEq of calcium infused over a 24 hour period.²³

In patients with life-threatening poisoning and particularly HF inhalation, simultaneous administration of IV, oral, and nebulized 2.5% calcium gluconate can be given to facilitate the availability of the maximum amount of calcium. To prepare nebulized calcium gluconate, mix 1.5 mL of 10% calcium gluconate solution with 4.5 mL of sterile water or 0.9% sodium chloride to make a 2.5% solution. For moderate to severe burns (generally from HF concentrations >10%) of the fingers and hands, an intraarterial calcium infusion may be more effective than local or IV therapy, although it is more invasive^{51,58,64,66,67} and more hazardous.⁵⁸ A calcium gluconate solution (10 mL of 10%) mixed in 40 to 50 mL of 5% dextrose solution can be infused intraarterially over 4 hours followed by subsequent 40 to 50 mL intraarterial infusions after 4 hours when pain persists.⁶⁶ Serum calcium, potassium, and magnesium concentrations should be carefully monitored in all severely poisoned patients.

Hypocalcemia from the ingestion of household fluoride-containing dental products (eg, dental fluoride rinses, sodium fluoride tablets) rarely occurs and is dose dependent. Hypocalcemia and significant morbidity and mortality occur with ingestion of industrial strength fluoride cleaners or fluoride releasers (eg, ammonium bifluoride used for cleaning white wall tires). Patients with these exposures should be treated with calcium in a manner similar to the hypocalcemia from other causes.

ROLE IN HYPOCALCEMIA SECONDARY TO PHOSPHATES

Inappropriate use of oral and rectal phosphates, as a laxative can result in hypocalcemia, hyperphosphatemia, and hyperkalemia with resultant morbidity and mortality.⁴ IV calcium may be needed for life threatening hypocalcemia. However, since administration of calcium in the presence of hyperphosphatemia risks precipitation of calcium phosphate throughout the body, hemodialysis and other therapies should be considered in non-life-threatening cases.

ROLE IN HYPERMAGNESEMIA

Hypermagnesemia causes both direct and indirect depression of skeletal muscle, resulting in neuromuscular blockade, loss of reflexes, and profound muscular paralysis, with attendant ventilatory failure (Chap. 19).^{36,46} Excess magnesium also causes prolongation of the PR interval and QRS complex on electrocardiography (ECG) and depression of the sinoatrial node, leading to a bradycardic arrest. IV calcium serves as a physiologic antagonist to these adverse effects of magnesium (Table A29–1).

ROLE IN HYPERKALEMIA

Hyperkalemia causes significant myocardial depression. The resultant ECG changes are well defined. The height of the T wave increases and lengthening of the PR interval and QRS complex occur; ultimately, a sine wave pattern precipitating cardiac arrest may occur (Chaps. 16 and 19).²¹ Calcium makes the membrane threshold potential less negative, restoring the resting and threshold potential difference so that a larger stimulus is required to depolarize the cell from the resting potential. This stabilization antagonizes the hyperexcitability caused by modest hyperkalemia. However, when severe hyperkalemia exists, voltage-gated sodium channels are inactivated and cannot be depolarized, regardless of the strength of the impulse. Calcium may transform the voltage sensor of the sodium channel from inactive to closed, thus allowing the sodium channel to be opened with depolarization.²⁹ If hyperkalemia is secondary to the toxic effects of cardioactive steroids on the Na^+/K^+ -adenosine triphosphatase (ATPase) pump, IV calcium can potentially exacerbate an already excessive intracellular calcium concentration, making IV calcium potentially harmful (Chap. 65).²¹

ADVERSE EFFECTS AND SAFETY ISSUES

Severe hypercalcemia is defined by a serum calcium concentration greater than 14.0 mg/dL (3.5 mmol/L) in a patient with a normal albumin concentration. The adverse effects of hypercalcemia (independent of the rate of administration) include nausea, vomiting, constipation, ileus, hypertension if intravascular volume is adequate, polyuria, polydipsia, cognitive difficulties, hyporeflexia, coma, and enhanced sensitivity to cardioactive steroids.⁶ Significant hypercalcemia may lead to myocardial depression. The symptoms exhibited depend on the patient's age, rate of increase in the serum calcium concentration, and duration of the hypercalcemia.⁶

Neither calcium chloride nor calcium gluconate should be combined and administered intravenously with sodium bicarbonate because calcium carbonate, a precipitate, is formed. Calcium chloride is an acidifying salt and is extremely irritating to tissue. It should never be given intramuscularly, subcutaneously, or perivascularly.^{21,45} Calcium gluconate is less irritating, but care should also be taken to avoid extravasation. The best reason for choosing calcium gluconate in almost all clinical situations is that the tissue risk is far less. If extravasation should occur, subcutaneous injection of aliquots of hyaluronidase can be injected around the site (Special Considerations: SC4).

PREGNANCY AND LACTATION

Calcium injection is in Food and Drug Administration pregnancy category C. Animal reproduction studies have not been conducted. Benefit is expected to outweigh risk when indicated as life saving therapy for the mother. Calcium is excreted in breast milk but is likely safe.

DOSING AND ADMINISTRATION

IV calcium must be administered slowly, at a rate not exceeding 0.7 to 1.8 mEq/min or one 10 mL vial of calcium chloride or three 10 mL vials of calcium gluconate over 10 minutes in adults, unless the patient is in extremis. More rapid administration may lead to vasodilation, hypotension, bradycardia, dysrhythmias, syncope, and cardiac arrest.^{7,15,35,45,61} In cases of life threatening hypocalcemia or for a patient in extremis, a slow IV push may be required. Repeat doses may be administered as clinically indicated. Total and ionized calcium should be monitored.

Topical, nebulized, and intraarterial administration is specifically addressed in the section on the role of calcium in the management of HF.

FORMULATION AND ACQUISITION

A variety of calcium salts are available for parenteral administration. The two most commonly used are calcium chloride (10%) and calcium gluconate (10%) (Table A29-1).

A topical calcium gluconate gel (Calgonate) (2.5%) 25 g is available. Topical preparations can be extemporaneously made as described in the section on role in hypocalcemia secondary to HF. A commercially prepared calcium gluconate 1% solution (Calgonate emergency eyewash) is available in 120 mL squirt bottles.

SUMMARY

- IV calcium infusion is an effective antidote for the hypocalcemia induced by ethylene glycol, HF, and fluoride releasing xenobiotics.
- Equivalent molar calcium doses found in appropriate volumes of calcium gluconate and calcium chloride deliver

equal amounts of ionized calcium.

- Calcium serves as a physiologic antagonist to the cardiac and or neurologic effects of hypermagnesemia and hyperkalemia and counteracts some of the effects of CCB overdoses.
- Calcium may have some benefit in the treatment of β -adrenergic antagonist overdoses.
- Great care must be taken to avoid extravasation, as calcium chloride in particular can cause tissue necrosis.
- ECG monitoring and frequent ionized calcium concentration measurements are required to prevent iatrogenic toxicity.
- Although most clinical experience involves IV use, advances in intraarterial, topical, inhalational, and intraosseous calcium therapy may offer unique potential advantages.

HISTORY AND EPIDEMIOLOGY

The modern world could not exist without hydrocarbons. Virtually everything we touch is either coated with or made up primarily of hydrocarbon products. Organic chemistry originated during the Industrial Revolution, evolving largely due to advances in coal tar technology. In the coking process, bituminous (soft) coal is heated to liberate coal gas. This gas contains volatile hydrocarbons that can be captured and separated into a variety of natural gases. The viscous residue left over from the coking process forms coal tar, which can, in turn, be distilled into kerosene and other hydrocarbon mixtures.

Over the years, petroleum has replaced coal tar as the principal source of commercial organic compounds. Crude oil processing involves heating to a set temperature within processors that separate (distill) hydrocarbon fractions by vapor (or boiling) point. Because of the relationship between boiling point and molecular weight, distillation roughly divides hydrocarbons into like sized molecules. The most volatile fractions come off early as gases, and these are used primarily as heating fuels. The least volatile fractions (larger than about 10 or 12 carbons) are used chiefly for lubricants or as paraffins, petroleum jelly, or asphalt. The remaining mid sized distillation fractions (5 to 10 carbons) are those most commonly used in combustion fuels and as solvents. Petroleum distillates are used as chemical feedstocks and as precursors or intermediates in feedstock production.

For decades in the United States, kerosene ingestion in children was a major public health concern.¹²¹ Only through public education, consumer product safety initiatives, and modernization of the use and distribution of cooking and heating fuels has this problem been largely eliminated. However, in the developing world, these same challenges have yet to be resolved, with large numbers of children ingesting kerosene from poorly labeled and poorly secured containers.^{1,18,19,46,63,93,109,125,137,159}

Recent public attention and debate surrounds the potential for hydrocarbon exposures following environmental spills. Even more controversial is the practice of “induced hydraulic fracturing” of rock or shale, commonly called “fracking.” Fracking is performed on up to 60% of oil and gas wells drilled today, to liberate pockets of trapped gas or oil from within the fractured rock.^{103,165} The intent is to capture and collect trapped hydrocarbons, but some escape into nearby aquifers, thereby entering water supplies or otherwise contaminating human environments. Critics are concerned about the composition of the hydraulic fluids used, as these may be comprised mainly of methanol, ethylene glycol, benzene, or other hydrocarbons. Components of these fluids are found in area groundwater, with resultant risk of human exposure^{62,175} and untoward health effects.⁹⁹

The true epidemiology of hydrocarbon exposure and illness is difficult to ascertain from available data sources. But three populations appear to be at particular risk for hydrocarbon related illness. These are children who suffer unintentional exposures, often ingestion with pulmonary aspiration; workers with occupational exposures, often inhalational and dermal; and adolescents or young adults who intentionally abuse solvents by inhalation. People in specific occupations who are at risk for exposure include petrochemical workers, plastics and rubber workers, printers, laboratory workers, painters, and hazardous waste workers. Most hydrocarbon exposures do not involve ingestion, and most do not result in illness. Exposures may range from self-pumping gasoline, to painting a spare bedroom, or to applying or removing fingernail polish. Because hydrocarbon solvents are often volatile, inhalation is extremely common. Lipid solubility results in dermal absorption when skin is exposed.⁶⁵ Data from US poison centers suggest that about 30% of reported exposures to hydrocarbons were in children younger than 6 years of age (Chap. 136). Largely not captured in these data is an alarming rate of intentional misuse of volatile solvents by young people, which is discussed in more depth in Chap. 84.

Most commonly encountered hydrocarbons are mixtures of compounds, often obtained from a common petroleum distillation fraction. The many applications for these in consumer and household products include paints and thinners, furniture polish, lamp oils, and lubricants. Table 108–1 lists frequently encountered hydrocarbon compounds and their properties. This chapter focuses principally on toxicity of hydrocarbons present in these commercially available mixtures. Individual hydrocarbons are discussed only when they are commonly available in purified form, or when specific xenobiotics result in unique toxicologic concerns.

TABLE 108–1. Classification and Viscosity of Common Hydrocarbons

Compound	Common Uses	Viscosity (SUS) ^a
Aliphatics		
Gasoline	Motor vehicle fuel	30
Naphtha	Charcoal lighter fluid	29
Kerosene	Heating fuel	35
Turpentine	Paint thinner	33
Mineral spirits	Paint and varnish thinner	30–35
Mineral seal oil	Furniture polish	30–35
Heavy fuel oil	Heating oil	>450
Aromatics		
Benzene	Solvent, reagent, gasoline additive	31
Toluene	Solvent, spray paint solvent	28
Xylene	Solvent, paint thinner, reagent	28
Halogenated		
Methylene chloride	Solvent, paint stripper, propellant	27
Carbon, tetrachloride	Solvent, propellant refrigerant	30
Trichloroethylene	Degreaser, spot remover	27
Tetrachloroethylene	Dry cleaning solvent, chemical intermediate	28

^aDirect values for kinematic viscosity in Saybolt universal seconds (SUS) were not available for the following compounds: naphtha, xylene, methylene chloride, carbon tetrachloride, trichloroethylene, perchloroethylene, and toluene. SUS was calculated by converting from available measurements in centipoise viscosity and/or centistokes viscosity using the following conversions: the value in centistokes is estimated by dividing centipoise by density at 68°F (20°C); SUS is approximated from centistokes using $y = 3.2533x + 26.08$ ($R^2 = 0.9998$). Centipoise viscosity for naphtha was estimated from the value for butylbenzene. Centipoise viscosity for xylene is the average of *o*-, *m*-, and *p*-xylene.

CHEMISTRY

A hydrocarbon is an organic compound made up primarily of carbon and hydrogen atoms, typically ranging from 1 to 60 carbon atoms in length. This definition includes products derived from plants (pine oil, vegetable oil), animal fats (cod liver oil), natural gas, petroleum, or coal tar. There are two basic types of hydrocarbon molecules, aliphatic (straight or branched chains) and cyclic (closed ring), each with its own subclasses. The aliphatic compounds include the paraffins (alkanes, with a generic formula C_nH_{2n+2}); the olefins (alkenes have one double bond and alkadienes have two double bonds); acetylenes (alkynes) with at least one triple bond; and the acyclic terpenes (polymers of isoprene, C_5H_8). Some aliphatic compounds have branches in which the subchain also contains carbon atoms; both the chain and branches are essentially straight.

The cyclic hydrocarbons include alicyclic (three or more carbon atoms in a ring structure, with properties similar to the aliphatics), and aromatic compounds, as well as the cyclic terpenes. The alicyclics are further divided into cycloparaffins (naphthenes) such as cyclohexane, and the cycloolefins (two or more double bonds) such as cyclopentadiene.

Saturated hydrocarbons contain carbon atoms that exist only in their most reduced state. This means that each carbon is bound to either hydrogen or to another carbon, with no double or triple bonds present. Conversely, unsaturated compounds are those with hydrogens removed, in which double or triple bonds exist.

Solvents are a heterogeneous class of xenobiotics used to dissolve and provide a vehicle for delivery of other xenobiotics. The most common industrial solvent is water. The common solvents most familiar to toxicologists are organic solvents (containing one or more carbon atoms), and most of these are comprised of hydrocarbons. Most are liquids in the conditions under which they are used. Specifically named solvents (Stoddard solvent, white naphtha, ligroin) represent mixtures of hydrocarbons emanating from a common petroleum distillation fraction.

Aromatic hydrocarbons are divided into the benzene group (one ring), naphthalene group (two rings), and the anthracene group (three rings). Polycyclic aromatic hydrocarbons (polynuclear aromatic hydrocarbons) have multiple, fused benzenelike rings. Aromatic organic compounds may also be heterocyclic (where oxygen or nitrogen substitutes for carbon in the ring). Structurally, all of these molecules are flat, with reactive electron clouds above and below the ring.

The cyclic terpenes are the principal components of the variety of plant-derived essential oils ([Chap. 43](#)), often

providing color, odor, and flavor. Limonene in lemon oil, menthol in mint oil, pinene in turpentine, and camphor are all terpenes.

Physical properties of hydrocarbons vary by the number of carbon atoms and by molecular structure. Unsubstituted, aliphatic hydrocarbons that contain up to 4 carbons are gaseous at room temperature, 5 to 19 carbon molecules are liquids, and longer-chain molecules tend to be tars or solids. Branching of chains tends to destabilize intermolecular forces, so that less energy is required to separate the molecules. The result is that, for a given molecular size, highly branched molecules have lower melting and boiling points and tend to be more volatile.

The various definitions of paraffin warrant discussion. In chemistry, paraffin is a general term for any alkane. In North American common use, paraffin describes either medicinal paraffin or paraffin wax. Medicinal paraffin is the same as mineral oil, a viscous mixture of longer-chained alkanes (typically 15–50 carbon atoms per molecule) derived from a petroleum source. The molecules in mineral oil exhibit considerable branching, making it a viscous liquid at room temperature and pressure. Molecules in paraffin wax are nearly identical to these in size, but less branching increases the number of intermolecular interactions, forming a waxy/solid at room temperature. Outside North America, the term paraffin often refers to kerosene—a mixture of medium-chain alkanes typically used for lighting and heating.

Gasoline is a mixture of alkanes, alkenes, naphthenes, and aromatic hydrocarbons, predominantly 5 to 10 carbon atoms in size. Gasoline is separated from crude oil in particular distillation fractions and then usually blended with several other fractions in refinery processors. More than 1500 individual molecular species may be present in commercial grades, but most analytical methods isolate only 150 to 180 constituent compounds in gasoline. Notably, n-hexane is present at up to 6%, and benzene is present between 1% and 6%, depending on the origin and processing technique. A number of additives may go into the final formulation: alkyl leads, ethylene dichloride, and ethylene dibromide in leaded gasoline, and oxygenates such as methyl t-butyl ether (MTBE), as well as methanol and ethanol.

Organic halides contain one or more halogen atoms (fluorine, chlorine, bromine, iodine) usually substituted for a hydrogen atom in the parent structure. Examples include chloroform, trichloroethylene, and the freons.

Oxygenated hydrocarbons demonstrate toxicity specific to the oxidation state of the carbon, as well as to the atoms adjacent to it (the “R” groups). The alcohols are widely used as solvents in industry and in household products. Their toxicity is discussed in Chaps. 80 and 109. Ethers contain an oxygen atom bound on either side by a carbon atom. Acute toxicity from ethers tends to mirror that of the corresponding alcohols. Aldehydes and ketones contain one carbon–oxygen double bond ($C=O$), the former at a terminal carbon, the latter somewhere in the middle. Organic acids, esters, amides, and acyl halides represent more oxidized states of carbon; human toxicity is agent specific.

Phenols consist of benzene rings with an attached hydroxyl (alcohol) group. The parent compound, phenol, has only one hydroxyl group attached to benzene. The toxicity of phenol can be dramatically altered by addition of other functional groups to the benzene ring (Chap. 104). Cresols, catechols, and salicylate are examples of substituted phenols.

A variety of amines, amides, nitroso and nitro compounds, as well as phosphates, sulfites, and sulfates are used commercially and industrially. The addition of these functional groups to hydrocarbons dramatically alters the characteristics, including the toxicity of the compound.

PHARMACOLOGY

The effects of hydrocarbons on humans are chiefly related to interactions with lipid bilayers in cellular membranes. Inhaled hydrocarbon vapor depresses consciousness. As such, acute central nervous system (CNS) toxicity from occupational overexposure or recreational abuse parallels the effect of administering an inhaled general anesthetic. The concentration of volatile anesthetic that produces loss of nociception in 50% of patients defines the minimum alveolar concentration (MAC) required to induce anesthesia. Similarly, inhaled solvent vapor produces unconsciousness in 50% of subjects, when the partial pressure in the lung reaches its median effective dose (ED_{50}). The ED_{50} in occupational terms is effectively the same as the MAC in anesthesiology terms (Chap. 68). Virtually all patients will be anesthetized when the partial pressure is raised 30% above the MAC ($MAC \times 1.3$). If ventilation is not supported, death typically occurs when the concentration reaches two to four times the MAC.⁸⁵ Dose–response curves suggest that essentially no individual will be rendered unconscious by an inhaled dose 30% below the MAC. Nonetheless, impaired cognitive and motor function may occur at much lower doses.²³

The physical property of an inhaled anesthetic that correlates most closely with its ability to extinguish nociception is its lipid solubility. Inhalational exposure to lipid-soluble solvents, such as aromatic, aliphatic, or chlorinated hydrocarbons, is more likely to cause acute and chronic CNS effects than exposure to water-soluble hydrocarbons such as alcohols, ketones, and esters. The Meyer-Overton hypothesis, proposed more than 100 years ago, implies that an anesthetic dissolves into some critical lipid compartment of the CNS, causing inhibition of neuronal transmission. According to this hypothesis, the target structure for general anesthetics is the neuronal lipid membrane itself.⁶⁶

Unfortunately, this hypothesis is likely too simplistic. Numerous protein receptor interactions also occur. Halothane, isoflurane, sevoflurane, enflurane, and desflurane inhibit fast sodium channels.¹¹⁷ Toluene, trichloroethylene,

perchloroethylene, and others inhibit neuronal calcium currents.^{114,135} The halogenated hydrocarbons increase the outward potassium rectifying current.¹³⁶ Specific ligand-receptor interactions occur,⁴³ such as the inhibition of receptor function at nicotinic,¹⁶⁷ and at glutamate receptors,⁴² as well as enhancement of type-A γ -aminobutyric acid (GABA_A) and glycine receptor currents.¹⁷ Independent of other mechanisms, halogenated hydrocarbons appear to decrease exocytosis of neuronal synaptic vesicles.⁶⁸

Pharmacodynamic properties of inhaled hydrocarbons and other volatile xenobiotics (Chap. 68) suggest some receptor–ligand interaction, and a growing body of evidence suggests that the Meyer-Overton hypothesis cannot explain the many neurochemical activities demonstrated by this broad class of xenobiotics.⁷⁰ Perhaps a more elegant approach to the lipid bilayer interaction has been termed the “modern lipid hypothesis.” The hypothesis is thermodynamically derived, purporting an increase in lateral pressure on protein receptors within the neuronal bilayer. Lateral pressure leads to conformational changes in membrane ion channels, modulating the capacity for activation.³² While this hypothesis is mechanistically plausible and thermodynamically defensible, no in vitro or in vivo work has yet substantiated it. Thus, to date, no single mechanism fully explains the pharmacologic and toxicologic activity of volatile hydrocarbons on neuronal tissues.

TOXICOKINETICS

Hydrocarbons are variably absorbed into human systems by ingestion, inhalation, or dermal routes. Human toxicokinetic data are lacking for most of these xenobiotics, so much of our understanding derives from in vitro studies and animal research. Partition coefficients, in particular, are useful predictors of the rate and extent of the absorption and distribution of hydrocarbons into tissues. A partition coefficient for a given chemical species is the ratio of concentrations achieved between two different media at equilibrium. The blood-to-air, tissue-to-air, and tissue-to-blood coefficients directly relate to the pulmonary uptake and distribution of hydrocarbons. The tissue-to-blood partition coefficient is commonly derived by dividing the tissue-to-air coefficient by the blood-to-air coefficient.^{55,120} The higher the value, the greater the potential for distribution into tissue. Table 108–2 lists partition coefficients for commonly encountered hydrocarbons. Where human data are limited, rat data is presented in the table, because human and rat data often correlate.¹²⁰

TABLE 108–2. Kinetic Parameters of Selected Hydrocarbons

	Partition Coefficients ^a			<i>t</i> _{1/2}		Elimination	Relevant Metabolites
	Blood/Air	Fat/Air	<i>a</i>		<i>β</i>		
Aliphatics							
<i>n</i> -Hexane	2.29	159	0.17 hours		1.7 hours	10%–20% exhaled; liver metabolism by CYP2E1	2-Hexanol, 2,5-hexanedione, γ -valerolactone
Paraffin/tar	Not absorbed or metabolized		—			—	—
Aromatics							
Benzene	8.19	499	8 hours		90 hours	12% exhaled; liver metabolism to phenol	Phenol, catechol, hydroquinone, and conjugates
Toluene	18.0	1021	4–5 hours		15–72 hours	Extensive liver extraction and metabolism	80% metabolized to benzyl alcohol; 70% renally excreted as hippuric acid
<i>o</i> -Xylene	34.9	1877	0.5–1 hour		20–30 hours	Liver CYP2E1 oxidation	Toluic acid, methyl hippuric acid
Halogenated							
Methylene chloride	8.94	120	Apparent <i>t</i> _{1/2} of COHb 13 hours		0.7 hours	92% exhaled unchanged. Low doses metabolized; high doses exhaled. Two liver metabolic pathways	(a) CYP2E1 to CO and CO ₂ (b) Glutathione transferase to CO ₂ , formaldehyde, formic acid
Carbon tetrachloride	2.73	359	~1.5 hours		1.5–8 hours	Liver CYP2E1, some lung exhalation (dose-dependent)	Trichloromethyl radical, trichloromethyl peroxy radical, phosgene
Trichloroethylene	8.11	554	3 hours		30 hours	Liver CYP2E1—epoxide intermediate; trichloroethanol is glucuronidated and excreted	Chloral hydrate, trichloroethanol, trichloroacetic acid
1,1,1-Trichloroethane	2.53	263	0.7 hours		53 hours	91% exhaled; liver CYP2E1	Trichloroacetic acid, trichloroethanol
Tetrachloroethylene	10.3	1638	2.7 hours		33 hours	80% exhaled; liver CYP2E1	Trichloroacetic acid, trichloroethanol

^afat/blood partition coefficient is obtained by dividing the fat/air coefficient by the blood/air coefficient, as determined in rat models. All coefficients are determined at 38.6°C (101°F).

Inhalation is a major route of exposure for most volatile hydrocarbons. Most cross the alveolar membrane by passive diffusion. The driving force is the difference in vapor concentration between the alveolus and the blood. The absorbed dose is determined by the air concentration, duration of exposure, minute ventilation, and the blood-to-air partition coefficient. Hydrocarbons that are highly soluble in blood and tissues are readily absorbed, and blood concentrations rise rapidly following inhalation exposure. While aromatic species are generally well absorbed, absorption of aliphatic hydrocarbons varies by molecular weight: aliphatic hydrocarbons with between 5 and 16 carbons are readily absorbed through inhalation, whereas those with more than 16 carbons are less extensively absorbed.

Absorption of aliphatic hydrocarbons through the digestive tract is inversely related to molecular weight, ranging from complete absorption at lower molecular weights, to approximately 60% for C-14 hydrocarbons, 5% for C-28 hydrocarbons, and essentially no absorption for aliphatic hydrocarbons with more than 32 carbons. Oral absorption of aromatic hydrocarbons with between 5 and 9 carbons ranges from 80% to 97%. Oral absorption of aromatics with more than 9 carbons is poorly characterized, as data are lacking.

While the skin is a common area of contact with solvents, the dose of dermally absorbed hydrocarbons is quite small relative to that through other routes such as inhalation. The skin is comprised of both hydrophilic (proteinaceous portion of cells) and lipophilic (cell membranes) regions (Chap. 18). While many hydrocarbons can remove lipids from the stratum corneum, permeability is not simply the result of lipid removal; permeability also increases with hydration of the skin. The rate of skin absorption is highest when xenobiotics have a water-to-lipid partition coefficient near one. Solvents that contain both hydrophobic and hydrophilic moieties (eg, glycol ethers, dimethylformamide, dimethylsulfoxide) are particularly well absorbed through skin. Other factors that determine penetration across the skin include the thickness of the skin layer, the difference in concentration of the solvent on either side of the epithelium, the diffusion constant, and skin integrity (ie, normal vs. cut or abraded).

The dose absorbed through skin is proportional to the exposed surface area and the duration of contact. Although highly volatile compounds may have a short duration of skin contact because of evaporation, skin absorption can also occur from contact with hydrocarbon vapor. In studies with human volunteers exposed to varying concentrations of hydrocarbon vapors, the dermal dose accounted for only 0.1% to 2% of the inhalation dose. With massive exposure (eg, whole-body immersion), dermal absorption may contribute significantly to toxicity. Significant dermal absorption with resultant toxicity is described with carbon tetrachloride,⁷⁴ tetrachloroethylene,⁶⁵ and phenol.⁹¹

Once absorbed into the central compartment, hydrocarbons are distributed to target and storage organs based on their

tissue-to-blood partition coefficients and on the rate of perfusion of the tissue with blood. During the onset of systemic exposure, hydrocarbons accumulate in tissues that have tissue/blood coefficients greater than 1 (eg, for toluene, the fat-to-blood partition coefficient is 60). [Table 108–2](#) lists the distribution half-lives of selected hydrocarbons.

Hydrocarbons can be eliminated from the body unchanged, for example, through expired air, or can be metabolized to more polar compounds, which are then excreted in urine or bile. [Table 108–2](#) lists the blood elimination half-lives (for first-order elimination processes) and metabolites of selected hydrocarbons. Some hydrocarbons are metabolized to toxic compounds (eg, methylene chloride, carbon tetrachloride, n-hexane, methyl-n-butyl ketone). The specific toxicities of these metabolites are discussed later in this chapter.

PATHOPHYSIOLOGY AND CLINICAL FINDINGS

Respiratory

Several factors are classically associated with pulmonary toxicity after hydrocarbon ingestion. These include specific physical properties of the xenobiotics ingested, the volume ingested, and the occurrence of vomiting. Physical properties of viscosity, surface tension, and volatility are primary determinants of aspiration potential.

Dynamic (or absolute) viscosity is the measurement of the ability of a fluid to resist flow. This property is measured with a rheometer and is typically given in units of pascal-seconds. More frequently, engineers work with kinematic viscosity, measured in square millimeters per second, or centistokes. Dynamic viscosity is converted to kinematic viscosity by dividing the dynamic viscosity by the density of the fluid. An older system for measuring viscosity was initially popularized by the petroleum industry and expresses kinematic viscosity in units of Saybolt Universal seconds (SUS). Unfortunately, many policy statements were developed in an era when SUS units were popular, and many still describe viscosity in SUS units. Various look-up tables and calculators are available to convert kinematic viscosity to SUS units. [Table 108–1](#) shows kinematic viscosity of common hydrocarbons, measured in SUS. A unit conversion approximation is given in the table's footnote.

Hydrocarbons with low viscosities (<60 SUS; eg, turpentine, gasoline, naphtha) have a higher tendency for aspiration in animal models. The US Consumer Products Safety Commission issued a rule in 2001, requiring child-resistant packaging for products that contain 10% or more hydrocarbon by weight and have a viscosity less than 100 SUS.

Surface tension is a cohesive force generated by attraction due to the Van der Waals forces between molecules. This influences adherence of a liquid along a surface (“its ability to creep”). The lower the surface tension, the more effectively the liquid will creep, producing a higher aspiration risk.⁵⁷

Volatility is the tendency for a liquid to become a gas. Hydrocarbons with high volatility tend to vaporize, displace oxygen, and potentially lead to transient hypoxia.

Early reports conflicted in their attempts to relate risk of pulmonary toxicity (1) to the amount of hydrocarbon ingested or (2) to the presence or absence of vomiting. One prospective study addressed both these variables. The cooperative kerosene poisoning (COKP) study was a multicenter study that enrolled 760 patients with hydrocarbon ingestion. Of these, 409 individuals could provide an estimate of the amount ingested. Patients who reportedly ingested more than 30 mL had a 52% chance of developing pulmonary complications, compared with 39% of those who ingested less than 10 mL. Risk of central nervous complications was 41%, compared with 24% using the same criterion. There was a 53% incidence of pulmonary toxicity when vomiting occurred, compared with 37% when there was no history of vomiting.¹²¹ While this knowledge may help modify the index of suspicion regarding possible pulmonary toxicity, none of these parameters is completely predictive. Severe hydrocarbon pneumonitis may occur after ingestion of “low-risk” hydrocarbons.¹³¹ Patients may develop severe lung injury after low-volume (<5 mL) ingestions, as well as after ingestions with no history of coughing, gagging, or vomiting.⁸

It is widely held that aspiration is the main route of injury from ingested simple hydrocarbons. The mechanism of pulmonary injury, however, is not fully understood. Intratracheal instillation of 0.2 mL/kg of kerosene causes physiologic abnormalities in lung mechanics (decreased compliance and total lung capacity) and pathologic changes such as interstitial inflammation, polymorphonuclear exudates, intraalveolar edema and hemorrhage, hyperemia, bronchial and bronchiolar necrosis, and vascular thrombosis.⁶¹ These changes most likely reflect both direct toxicity to pulmonary tissue and disruption of the lipid surfactant layer.¹⁷¹

Most patients who develop pulmonary toxicity following hydrocarbon ingestion will have an initial episode of coughing, gagging, or choking. This usually occurs within 30 minutes after ingestion and is presumptive evidence of aspiration. The majority of patients who have respiratory signs and symptoms in addition to the initial history of gagging, choking, and coughing develop radiographic pneumonitis. Pulmonary toxicity may manifest as crackles, rhonchi, bronchospasm, tachypnea, hypoxemia, hemoptysis, acute respiratory distress syndrome (hemorrhagic or nonhemorrhagic), or respiratory distress. Cyanosis develops in approximately 2% to 3% of patients. This may result from simple asphyxiant effects from volatilized hydrocarbons, from ventilation–perfusion mismatch, or, rarely, from methemoglobinemia (aniline, nitrobenzene, or nitrite-containing hydrocarbons). Clinical findings often worsen over the first several days but typically

resolve within a week. Death is distinctly uncommon and typically occurs after a severe, progressive respiratory insult marked by hypoxia, ventilation–perfusion mismatch, and barotrauma.^{75,92,179}

Intravenous (IV), subcutaneous, and even intrapleural injection of hydrocarbons are reported.^{45,129,163} Severe hydrocarbon pneumonitis may occur following IV exposure. Animal experiments show that intravascular hydrocarbons injure the first capillary bed encountered.^{127,173} The clinical course after IV hydrocarbon injection is comparable to that of aspiration injury.

Radiographic evidence of pneumonitis develops in 40% to 88% of patients admitted following aspiration.^{16,44,115} Findings can develop as early as 15 minutes or as late as 24 hours after exposure (Fig. 108–1).^{22,54,121,164} Chest radiographs performed immediately on initial presentation are not useful in predicting infiltrates in either symptomatic or asymptomatic patients.⁸ Ninety percent of patients who develop radiographic abnormalities do so by 4 hours postingestion.²² Clinical signs of pneumonia (eg, crackles, rhonchi) are evident in 40% to 50% of patients.⁴⁴ A small percentage (<5%) are completely asymptomatic after a period of observation, yet to have radiographic findings.⁸

A

B

C

FIGURE 108–1. Three sequential radiographs of a young girl with severe hydrocarbon aspiration. (A) Initial: Patchy densities appear in the basilar areas of both lung fields with increased interstitial markings and peribronchial thickening. (B) Day 2: More extensive diffuse alveolar infiltrates are apparent. (C) Day 6: Dense consolidation and atelectasis are evident in the right lower lobe. (Used with permission of Nancy Genieser, MD, Professor of Radiology, New York University.)

Specific radiologic findings include perihilar densities, bronchovascular markings, bibasilar infiltrates, and pneumonic consolidation.⁵⁸ Right-sided involvement occurs in 75% of cases and bilateral involvement in approximately 50%. Upper-lobe involvement is uncommon. Pleural effusions develop in 3% of cases, with one-third appearing within 24 hours.¹⁰⁰ Pneumothorax, pneumomediastinum, and pneumatoceles occur uncommonly.^{10,20,78} Initial radiographs after ingestion may reveal two liquid densities in the stomach, known as the “double-bubble” sign. This represents an air–fluid (hydrocarbon or water) and a hydrocarbon–water interface, as the hydrocarbon is not miscible with gastric (aqueous) fluid and may have

a specific gravity less than that of water.³⁸

Radiographic resolution does not correlate with clinical improvement but rather lags behind by several days to weeks. There are few reports of long-term follow-up on patients with hydrocarbon pneumonitis.^{64,154} Frequent respiratory tract infections are described after hydrocarbon pneumonitis, but these studies are not well controlled.^{54,157} Delayed formation of pneumatoceles may occur.^{20,78} Bronchiectasis and pulmonary fibrosis are reported but appear to be uncommon.^{60,124} In one study, 82% of patients examined 8 to 14 years after hydrocarbon-induced pneumonitis had asymptomatic minor pulmonary function abnormalities. The abnormalities were consistent with small-airway obstruction and loss of elastic recoil. The authors hypothesized that this group may be predisposed to chronic obstructive pulmonary disease.⁶⁴

Cardiac

The most concerning cardiac effect from hydrocarbon exposure is precipitation of dysrhythmias through myocardial sensitization.¹¹⁰ Malignant dysrhythmias may occur after exposure to high concentrations of volatile inhalants or inhaled anesthetics. Such events are described with all classes of hydrocarbons, but halogenated compounds are most frequently implicated, followed by aromatic compounds.^{13,126} Atrial fibrillation, ventricular tachycardias, junctional rhythms, ventricular fibrillation, and cardiac arrest are reported.^{29,105,111,126} This is termed the “sudden sniffing death syndrome.”¹⁴ Prolongation of the QT interval in some cases raises additional concern for the development of torsade de pointes.^{14,133}

Cardiac sensitization is incompletely understood.^{43,110,134} Halothane and isoflurane inactivate sodium channels,¹⁴² whereas chloroform and others attenuate potassium efflux through voltage-gated channels.¹³³ Sensitization may be mediated by slowed conduction velocity through membrane gap junctions. Dephosphorylation of connexin-43 results in a conformational change that increases gap junctional resistance. Halocarbons, in the presence of epinephrine, cause dephosphorylation of this gap junction protein, thereby increasing resistance and slowing conduction velocity in myocardial tissue.⁷⁶

Any route of exposure to hydrocarbons may result in cardiotoxicity. Classically, sudden death follows an episode of sudden exertion, presumably associated with an endogenous catecholamine surge.¹⁴ Tachydysrhythmias, cardiomegaly, and myocardial infarction are rarely reported after ingestion of hydrocarbons.^{72,144} A retrospective follow-up cohort of exposed methylene chloride workers did not find evidence of excess long-term cardiac disease.¹¹⁶

Central Nervous System

Transient CNS excitation may occur after acute hydrocarbon inhalation or ingestion, but more commonly, CNS depression or general anesthesia occurs.⁴⁴ In cases of aspiration, hypoxemia from pulmonary damage may contribute to CNS depression.^{95,174} Coma and seizures are reported in 1% to 3% of cases.^{115,124,178} Chronic occupational exposure or volatile substance use may lead to a chronic neurobehavioral syndrome, the painter’s syndrome, most notably described after toluene overexposure. Clinical features include ataxia, spasticity, dysarthria, and dementia, consistent with leukoencephalopathy.^{50–53} Autopsy studies of the brains of chronic toluene abusers show atrophy and mottling of the white matter, as though the lipid-based myelin were dissolved away. Microscopic examination shows a consistent pattern of myelin and oligodendrocyte loss with relative preservation of axons.⁸⁴ Animal models of toluene poisoning reveal norepinephrine and dopamine depletion. The severity and reversibility of this syndrome depends on the intensity and duration of toluene exposure.¹³² Infrequent exposure may produce no clinical neurologic signs, whereas severe (daily) use can lead to significant neurologic impairment after as little as 1 year, but more commonly after 2 to 4 years of continuous exposure. The specific cognitive and neuropsychological findings in toluene-induced dementia have been termed a white matter dementia.^{50–52}

Initial findings of white matter dementia include behavioral changes, impaired sense of smell, impaired capacity to concentrate, and mild unsteadiness of hand movements and gait. Further exposure leads to slurred speech, head tremor, poor vision, deafness, stiff-legged and staggering gait, and subsequent dementia. Physical findings may include nystagmus, ataxia, tremor, spasticity with hyperreflexia, plantar extension, deafness, impaired vision, and a broad-based, staggering gait. An abnormal brainstem auditory-evoked response appears to be a sensitive indicator of toluene-induced CNS damage. The electroencephalogram can show mild, diffuse slowing. Computed tomography in severe cases shows mild-to-moderate cerebellar and cortical atrophy. Magnetic resonance imaging (MRI) findings are consistent with white matter disease. Most cases show clinical improvement after 6 months of abstinence, although with moderate to severe abuse, improvement may be incomplete. While toluene abuse is addicting, withdrawal or abstinence syndrome is surprisingly uncommon and, when present, appears relatively benign.^{50–52}

Exposures in the occupational setting are rarely as extreme as those that occur with intentional volatile substance misuse. Given the significantly lesser exposures, the findings among workers overexposed to solvent concentrations above permissible exposure limits are often subclinical and detected primarily through neurobehavioral testing. In rare cases, however, a worker may be acutely overexposed to solvent concentrations that can produce acute CNS depression.

Repeated, symptomatic overexposures over a protracted period of time have the potential to lead to a chronic encephalopathy, as evident from the experience with solvent abusers.⁵¹

Peripheral Nervous System

Peripheral neuropathy is well described following occupational exposure to n-hexane or methyl-n-butyl ketone (MnBK).²⁵ This axonopathy results from a common metabolic intermediate, 2,5-hexanedione. The mechanism by which this intermediate causes peripheral neuropathy probably relates to decreased phosphorylation of neurofilament proteins, with disruption of the axonal cytoskeleton. Methyl ethyl ketone may exacerbate this neurotoxicity, probably by interfering with metabolic pathways of n-hexane and MnBK.^{7,130} Other organic solvents, such as carbon disulfide, acrylamide, and ethylene oxide, may cause a similar peripheral axonopathy.⁵⁹ Cranial and peripheral neuropathies are reported after acute and chronic exposure to trichloroethylene (TCE).^{77,90,151} Pathologically, TCE appears to induce a myelinopathy.^{48,59}

TCE exposure is associated with trigeminal neuralgia.^{34,47,90} Symptoms can develop within 12 hours of a single intense exposure and persist for many years.⁴⁸ Trigeminal nerve damage was documented by evoked potentials following 15 minutes of TCE inhalation.⁹⁰ Some evidence suggests that decomposition products or impurities in TCE may be responsible for cranial neuropathy.^{34,47,85}

Axonopathy from MnBK or n-hexane exposure typically begins in the distal extremities and progresses proximally (a classic, “dying-back” neuropathy) (Chap. 24). Exposure to one of these hydrocarbons should be considered in the differential diagnosis of the patient with Guillain-Barré syndrome (GBS), although sensory findings are present with MnBK and absent in GBS.¹⁴⁰ The longest axons appear to be affected initially, so that the patient manifests a “length-dependent polyneuropathy.” With discontinuation of exposure many of the effects reverse over weeks to months.^{69,80,122,177} Alternatively, the phenomenon of “coasting” may occur, in which neuropathy progresses for a time (weeks to months) after discontinuation of the toxic insult.¹⁴⁰ A reversible peripheral neuropathy occurred in 40% of chronic toluene abusers and was characterized by severe motor weakness without sensory deficits or areflexia.¹⁵⁰ It is unclear whether the toluene in this series might have been contaminated by n-hexane or MnBK.⁷

Gastrointestinal

Hydrocarbons irritate gastrointestinal mucous membranes. Nausea and vomiting are common after ingestion. As discussed earlier, vomiting may increase the risk of pulmonary toxicity.^{113,115} Hematemesis was reported in 5% of cases in one study,¹¹³ and gastrointestinal ulcerations are reported in animal studies⁸¹.

Hepatic

The chlorinated hydrocarbons (Table 108–1) and their metabolites are hepatotoxic. In most cases, activation occurs via a phase I reaction to form a reactive intermediate (Chap. 13). In the case of carbon tetrachloride, this intermediate is the trichloromethyl radical. This radical forms covalent bonds with hepatic macromolecules and may initiate lipid peroxidation.²⁷ Carbon tetrachloride causes centrilobular necrosis after inhalational, oral, or dermal exposure.¹⁰² Hepatotoxicity in animals has been ranked for common hydrocarbons as follows: carbon tetrachloride is greater than benzene, and trichloroethylene is greater than pentane.¹⁷² Vinyl chloride is a liver carcinogen, and trichloroethylene, tetrachloroethylene, and 1,1,1-trichloroethane are considered less acutely hepatotoxic than vinyl chloride.¹⁰² Hepatotoxicity rarely follows ingestion of petroleum distillates.⁷³ Hepatic injury, manifested as aminotransferase elevation and hepatomegaly, is usually reversible except in massive exposures.

Renal

Halogenated hydrocarbons such as chloroform, carbon tetrachloride, ethylene dichloride, tetrachloroethane, 1,1,1-trichloroethane, and TCE are nephrotoxic. Acute kidney injury (AKI) and distal renal tubular acidosis occur in some painters and volatile-substance abusers.¹⁵ Toluene causes a renal tubular acidosislike syndrome (see Toluene later in the chapter).

Hematologic

Hemolysis has been sporadically reported to occur following hydrocarbon ingestion.^{2,6,148} One retrospective study of 12 patients showed hemolysis in three individuals and disseminated intravascular coagulation in another.⁶ Although one patient required transfusion, hemolysis is usually mild and typically does not require red blood cell transfusion (also see discussion of the effects of benzene on bone marrow, under Benzene later in the chapter).

Immunologic

Hydrocarbons disturb the integrity of membrane lipid bilayers, causing swelling and increased permeability to protons and other ions. This alters the structural and functional integrity of the membrane. Changes in the lipid composition of the membrane occur, and membrane lipopolysaccharides and proteins are disturbed.¹³⁸ Resultant toxicity may directly destroy capillary endothelium.²⁶ Additionally, there appears to be significant basement membrane dysfunction, and this is postulated to underlie both alveolar and glomerular toxicity of hydrocarbons.¹⁴⁵ Immune mechanisms may account for basement membrane dysfunction in chronic exposures. Hydrocarbon exposure is suggested as one possible cause of the Goodpasture syndrome (immune dysfunction causing both pulmonary damage and glomerulonephritis),²⁴ although the association is not widely accepted. Measurable changes in immune function occur after hydrocarbon exposure,¹² but our knowledge of any clinical relevance is incomplete.

Dermatologic

Most hydrocarbon solvents cause nonspecific irritation of skin and mucous membranes. Repeated, prolonged contact can dry and crack the skin. The mechanism of dermal injury appears to be defatting of the lipid layer of the stratum corneum. Up to 9% of workers may develop eczematous lesions from dermal contact.¹⁷⁶ Limonene and turpentine contain sensitizers that can rarely result in contact allergy (Chap. 18).

Contact dermatitis and blistering may progress to partial-and even full-thickness burns.⁶⁷ Severity is proportional to duration of exposure. Hydrocarbons are irritating to skin. Acute, prolonged exposure can cause dermatitis and even full-thickness dermal damage.⁶⁷ Chronic dermal exposure to kerosene or diesel fuel can cause oil folliculitis.^{39,162} A specific cutaneous lesion called chloracne is associated with exposure to chlorinated aromatic hydrocarbons with highly specific stereochemistry such as dioxins and polychlorobiphenyls.

Soft tissue injection of hydrocarbon is locally toxic, leading to necrosis.⁴⁵ Secondary cellulitis, abscess formation, and fasciitis can occur. Infectious complications are treated by meticulous wound care, with surgical débridement as necessary. A particularly destructive injury involves high-pressure injection gun injury. These injuries typically involve the extremities, with high-pressure injection of grease or paint into the fascial planes and tendon sheaths. Emergent surgical débridement is necessary in most of these cases.^{49,107}

HYDROCARBONS WITH SPECIFIC AND UNIQUE TOXICITY

n-Hexane

Hexane is a six-carbon simple aliphatic hydrocarbon. It is a constituent of some brake-cleaning fluids, rubber cement, glues, spray paints, coatings, and silicones. Outbreaks of n-hexane-related neurotoxicity have occurred in printing plants, sandal shops, furniture factories, and automotive repair shops.³⁵ Human exposure occurs primarily by inhalation. Both n-hexane and MnBK are well-known peripheral neurotoxins that cause a classic “dying-back” peripheral polyneuropathy, beginning in a “stocking-glove” distribution.³⁶ Neurotoxicity does not appear to be directly caused by the parent compounds but results from a common metabolic intermediate—2,5-hexanedione. Toxicity appears related to the ability of this intermediate to form a ringed pyrrole structure, which causes decreased phosphorylation of neurofilament proteins, disrupting the axonal cytoskeleton.⁵⁹ Similar five- and seven-carbon species do not induce similar neurotoxicity, except those that are direct precursor intermediates in the metabolic pathway producing 2,5-hexanedione^{59,152} (Fig. 108–2).

FIGURE 108–2. The metabolism of both organic solvents n-hexane and methyl n-butyl ketone produces the same common metabolite, 2,5-hexanedione.

Methylene Chloride

Methylene chloride is commonly found in paint removers, cleansers, degreasers, and aerosol propellants. Like other halogenated hydrocarbons, it can rapidly induce general anesthesia by inhalation or ingestion. Unlike other hydrocarbon agents, methylene chloride and similar one carbon halomethanes such as methylene dibromide are metabolized by liver P450 2E1 mixed-function oxidase to carbon monoxide. Significant, delayed, and prolonged carboxyhemoglobinemia can occur^{3,123} (Table 108–2 and Chap. 125).

Carbon Tetrachloride

Carbon tetrachloride (CCl₄), although not actually a hydrocarbon, has been used as an industrial solvent and reagent. Its use in the United States has declined dramatically since recognition of its toxicity caused the Environmental Protection Agency to restrict its commercial use. Absorption occurs by all routes, including dermal. CCl₄ is an irritant to skin and mucous membranes and gastric mucosa when ingested. As in the case of other halogenated hydrocarbons, aspiration can result in pneumonitis, and systemic absorption may result in ventricular dysrhythmias.

CCl₄ exposures are hepatotoxic and nephrotoxic. Both occur more commonly with repetitive occupational exposure.^{74,155} Toxicity follows phase-I dehalogenation of the parent compound, which produces free radicals and causes lipid peroxidation and the production of protein adducts.²⁷ Localization of specific phase I hepatic enzymes in the centrilobular area of the liver results in regionalized (zone 3) centrilobular injury after CCl₄ exposure (Chap. 23). Hepatotoxicity is typically manifested as reversible aminotransferase concentration elevations with or without hepatomegaly. Cirrhosis is reported in both animal models and in humans with prolonged excessive exposures. Nephrotoxicity is less studied but may result from a similar mechanism. CCl₄ is a suspected human carcinogen.¹⁰⁸

Trichloroethylene

TCE is a commonly used industrial solvent, cleanser, and degreaser. Systemically absorbed TCE, as might occur in the occupational setting, may competitively inhibit aldehyde dehydrogenase. Concomitant ethanol consumption may result in a disulfiramlike reaction that has been termed “degreaser’s flush”¹⁴⁷ (Chap. 79).

TCE was used for years as a general anesthetic, and hundreds of disposal sites in the United States remain sources of ongoing human exposure. The use of TCE as a general anesthetic was abandoned because of associated acute cardiotoxicity. TCE is also hepatotoxic, neurotoxic, and nephrotoxic in humans and animals. TCE exposure is linked to the development of neurodegenerative diseases, such as parkinsonism.⁵⁶ Evidence suggests that TCE is a human carcinogen.^{112,118,146}

Benzene

Benzene is hematotoxic and associated with acute hemolysis or with the delayed development of aplastic anemia and acute myelogenous leukemia.^{4,86,101,119} Other aromatic hydrocarbons that are reported to cause similar hematologic effects most likely are contaminated with benzene. An excess risk of hematologic toxicity has not been demonstrated in groups with long-term exposure to toluene, xylene, or other aromatic hydrocarbons.^{9,40,128,166,170} Other hematologic malignancies also may be linked to benzene, including chronic myelocytic leukemia, myelodysplastic syndromes, and lymphoma.¹⁵⁶ Chromosomal changes are believed to provide a marker for carcinogenicity.¹⁶¹ Because of the carcinogenic risk, most benzene-based solvents have been removed from the US market, and the Occupational Safety and Health Administration has limited the permissible worker exposure concentration to 1 ppm.

Toluene

Toluene has essentially replaced benzene as the primary organic solvent in many commercial products. Many oil paints and stains primarily contain toluene as solvent. As such, it is readily available and readily abused as an inhalant. The CNS sequelae of chronic solvent inhalation are most frequently related to chronic toluene exposure.

Chronic toluene abuse can also cause a syndrome that resembles transient distal renal tubular acidosis (RTA).^{153,168} Although the mechanism is incompletely understood, the acidosis results in great part from the urinary excretion of hippuric acid (Table 108–2).^{33,79} Renal potassium loss may be severe and can result in symptomatic hypokalemia.⁷⁹ Clinical findings are a hyperchloremic metabolic acidosis, hypokalemia, and aciduria. Typically an associated transient azotemia occurs, as well as proteinuria and an active urine sediment.^{150,168} Some also report a proximal RTA, or the Fanconi

syndrome.^{106,168} A metabolic acidosis resulting from the metabolism of toluene to benzyl alcohol through alcohol dehydrogenase to benzoic acid may be an adequate explanation for the serum and urine acid–base disturbances.

Pine Oil and Terpenes

Pine oil is an active ingredient in many household cleaning products. It is a mixture of unsaturated hydrocarbons composed of terpenes, camphenes, and pinenes. The major components are terpenes, which are found in plants and flowers. Wood distillates including pine oil and turpentine are derived from pine trees. Patients who ingest pine oil often emit a strong pine odor. Wood distillates are readily absorbed from the gastrointestinal tract, and ingestion may cause CNS and pulmonary toxicity without aspiration.

The clinical features of pine oil ingestion can include CNS depression, respiratory failure, and gastrointestinal dysfunction, which are rarely fatal.^{83,169} Aspiration pneumonitis remains the primary clinical concern. Acute toxicity and management are similar to that of petroleum distillate ingestion. Rare reported complications of wood distillate ingestion include turpentine-associated thrombocytopenic purpura, AKI, and hemorrhagic cystitis.^{87,169}

Lipoid Pneumonia

Ingestion of low-viscosity hydrocarbons poses risk of pulmonary aspiration with subsequent acute pneumonitis. Conversely, viscous hydrocarbons rarely lead to pulmonary aspiration. Alternatively, inhalation of aerosolized oil droplets can occur in various occupational settings, and exogenous lipoid pneumonia may result. The most common xenobiotics involved are mineral or vegetable oils.^{21,89,96}

Initially, inhaled oil droplets are emulsified in the alveoli by surfactant, and then they are engulfed by alveolar macrophages. Unfortunately, the macrophages are unable to readily process the internalized, exogenous oil. Microscopically, persistent cytoplasmic droplets give a “foamy” appearance to these “lipophages” that may persist for weeks to years. Not uncommonly, the initial manifestations are limited or even subclinical, but once symptoms arise, illness may be prolonged from months to years. Ultimately, irreversible proliferative fibrosis may develop.¹⁴¹

Silicone-based polymers share structural similarities and some physical properties with long-chain hydrocarbons. Silicone polymers such as dimethicone exist as oily, viscous liquids at room temperature and are widely used as lubricants, antifoaming agents, and even as medicine and food additives. Pulmonary aspiration or inhalation of aerosolized silicone droplets causes clinical pneumonitis that is indistinguishable from that caused by their viscous hydrocarbon counterparts. The time course of lung injury is similarly protracted, and complications may be expected.¹³⁹

Tar and Asphalt Injury

Tar and asphalt injuries are common occupational hazards among construction workers. Asphalt workers are at risk for toxic gas exposure of hydrogen sulfide, carbon monoxide, propane, methane, and volatilized hydrocarbons.⁷¹ In addition, cutaneous exposure to these hot hydrocarbon mixtures can cause severe burns. The material quickly hardens and is very difficult to remove. However, immediate cooling with cold water is important to limit further thermal injury. Complete removal is essential to ensure proper burn management and to limit infectious complications. Attempts to remove hardened tar or asphalt mechanically often cause further damage. Dissolving the material with mineral oil, petroleum jelly, or antibacterial ointments are met with variable success. Surface-active agents combined with an ointment (De-Solv-it, Tween-80, Polysorbate 80) are more effective.^{41,149,160}

DIAGNOSTIC TESTING

Laboratory and ancillary testing for hydrocarbon toxicity should be guided by available information regarding the specific xenobiotic, the route of exposure, and the best attempt at quantifying the exposure. Inhalation or ingestion of hydrocarbons associated with pulmonary aspiration is most likely to result in pulmonary toxicity. The use of pulse oximetry, end-tidal CO₂, and arterial blood gas testing in this group of patients is warranted when clinically indicated. Early radiography is indicated in patients who are severely symptomatic; however, radiographs performed immediately after hydrocarbon ingestion have a poor predictive value for the occurrence of aspiration pneumonitis. In the asymptomatic patient, early radiography is not cost effective. Patients observed for 6 hours after an ingestion, who have adequate oxygenation, are not tachypneic, demonstrate no abnormal pulmonary findings, and have a normal chest radiograph obtained after the 6-hour observation period have a good medical prognosis with very low risk of subsequent deterioration.⁸

The choice of specific diagnostic laboratory tests to assess organ system toxicity or function following exposure to a hydrocarbon depends on the type, dose, and route of exposure, and on the assessment of the patient's clinical condition. Useful clinical tests may include pulse oximetry, end-tidal CO₂, and an ECG. Laboratory tests may include serum or urine electrolytes, venous or arterial blood gas, complete blood counts, and creatine phosphokinase as clinically indicated. If a

hydrocarbon has specific target organ toxicities (eg, benzene/bone marrow, CCl₄/liver, or n-hexane/peripheral nervous system), evaluating and monitoring target organ system function is indicated.

Specific diagnostic testing for hydrocarbon poisoning can include (a) bioassays for the specific hydrocarbon or its metabolites in blood, breath, or urine, or (b) assessment of toxicity. Bioassays for a hydrocarbon are seldom necessary for diagnosis or management of hydrocarbon poisoning in the emergency setting and rarely clinically available. Exceptions might include testing to assist in differential diagnosis (eg, testing for CCl₄ in a comatose patient with unexplained hepatic and renal toxicity or a carboxyhemoglobin determination in a paint stripper with chest pain), testing for worker compensation purposes (eg, testing for urinary trichloroethanol and trichloroacetic acid in a worker exposed to TCE with unexplained bouts of dizziness), or for forensic purposes (eg, sudden death in a huffer).

Chronic overexposures to hydrocarbons, as occur with volatile substance use, can result in persistent damage to the CNS. Damage can be detected and quantified using neuroimaging methods such as MRI or positron emission tomography. Major MRI findings in patients with chronic toluene abuse include atrophy, white matter T2 hyperintensity, and T2 hypointensity involving the basal ganglia and thalamus.³¹ Neurobehavioral testing can be used to detect subtle central nervous system effects following chronic occupational overexposures.

MANAGEMENT

Identification of the specific type, route, and amount of hydrocarbon exposure is rarely essential to achieve effective management.

Decontamination is one of the cardinal principles of toxicology, with priority that is second only to stabilization of the cardiopulmonary status. Safe decontamination can avoid further absorption and also avoids secondary casualties in those attempting to provide care. Protection of rescuers with appropriate personal protective equipment and rescue protocols is paramount, especially in situations where the victim has lost consciousness. The principle of removing the patient from the exposure (eg, vapor or gaseous hydrocarbon) or the exposure from the patient (eg, hydrocarbon liquid on skin or clothing), while protecting the rescuer, implies that personal protective equipment be considered at each level of the health care delivery system.

Exposed clothing should be removed and safely discarded as further absorption or inhalation of hydrocarbons from grossly contaminated clothing can worsen systemic toxicity. Decontamination of the skin should have a high priority in massive hydrocarbon exposures, particularly those exposures involving highly toxic hydrocarbons. Water alone may be ineffective in decontaminating most hydrocarbons, but early decontamination with soap and water may be adequate. The caregiver should remain aware that certain hydrocarbons are highly flammable and pose a fire risk to hospital staff ([Chap. 131](#)).

Several studies have attempted to evaluate the role of gastric decontamination after hydrocarbon ingestion. Results were largely inconclusive and the level of evidence, poor. In the subset of patients who were randomized to receive gastric lavage, 44% had pulmonary complications, compared with 47% of those who were not lavaged.¹²¹ Although available studies do not offer a conclusive answer to the question of gastric emptying after hydrocarbon ingestion, the high incidence of spontaneous emesis and the risk of aspiration essentially eliminate any consideration of gastric emptying in all but the rarest of cases.

Activated charcoal (AC) has limited ability to decrease gastrointestinal absorption of hydrocarbons and may distend the stomach and predispose patients to vomiting and aspiration.^{87,104} The use of AC may be justified in patients with mixed overdoses, but its role in isolated hydrocarbon ingestions appears very limited.

Antibiotics were once frequently administered in the setting of hydrocarbon pneumonitis to treat possible bacterial superinfection,¹⁶⁴ and they are still occasionally used today as fever and infiltrates are common. Although animal models rapidly demonstrate superinfection, prophylactic antibiotics only appear to alter pulmonary flora.²⁸ Prophylactic antibiotics did not affect length of stay or otherwise impact the outcome of 48 pediatric patients admitted for respiratory distress from hydrocarbon poisoning.⁷⁵ Similarly, in a randomized controlled study of pediatric patients suffering from kerosene-induced pneumonitis, prophylactic amoxicillin did not affect signs or symptoms, the rate of clinical deterioration (treatment failure), or duration of hospitalization.¹¹ However, antibiotic administration may be justified in severely poisoned patients. Ideally, sputum Gram stain or culture results should direct antibiotic use.

Corticosteroids, like antibiotics, have been prophylactically administered in the setting of hydrocarbon pulmonary toxicity.^{60,154} The rationale for their use is prevention and limitation of the pulmonary inflammatory response after hydrocarbon injury. Animal models do not show any benefit of corticosteroid administration^{5,143} and may increase the risk of bacterial superinfection. Furthermore, a controlled human trial failed to show a benefit from corticosteroid administration.⁹⁷ It is clear that corticosteroid use does not improve the acute course of hydrocarbon pulmonary toxicity, although some authors suggest improved outcome with delayed corticosteroid therapy there is little supporting evidence.^{78,82} Coupled with the possible increased risk of bacterial superinfection, corticosteroid administration in this

setting is not recommended.

Patients with severe hydrocarbon toxicity pose unique problems for management. Respiratory distress requiring mechanical ventilation in this setting may be associated with a large ventilation–perfusion mismatch. The use of positive end-expiratory pressure (PEEP) in this setting is often beneficial. However, very high levels of PEEP may be required, with subsequent increased risk of barotrauma.^{131,179} High-frequency jet ventilation (HFJV), using very high respiratory rates (220–260) with small tidal volumes, has helped to decrease the need for PEEP.³⁰ Patients who continue to have severe ventilation–perfusion mismatch despite PEEP and HFJV have benefited from extracorporeal membrane oxygenation (ECMO).^{131,179} ECMO appears to be a useful option in severe pulmonary toxicity after other treatments have failed. Early administration of surfactant may reduce pulmonary toxicity, but experience under these circumstances is limited.⁹⁸

Cyanosis is uncommon after hydrocarbon toxicity. Although this is most often caused by severe hypoxia, methemoglobinemia associated with hydrocarbon exposure is reported.^{37,88} The potential for methemoglobinemia should be investigated in patients who remain cyanotic following normalization of arterial oxygen tension ([Chap. 127](#)).

Hypotension in severe hydrocarbon toxicity raises additional concerns. The etiology of hypotension in this setting is often compromise of cardiac output because of high levels of PEEP. Hydrocarbons do not have significant direct cardiovascular effects, and decreasing the PEEP may improve hemodynamics. The use of β -adrenergic agonists such as dopamine, epinephrine, isoproterenol, and norepinephrine should be avoided if possible, as certain hydrocarbons predispose to dysrhythmias.^{13,110,126}

Management of dysrhythmias associated with hydrocarbon toxicity should include consideration of electrolyte and acid–base abnormalities such as hypokalemia and acidosis result from toluene, hypoxemia, hypotension, and hypothermia. Ventricular fibrillation poses a specific concern, as common resuscitation algorithms recommend epinephrine administration to treat this rhythm. If it is ascertained that the dysrhythmia emanates from myocardial sensitization by a hydrocarbon solvent, catecholamines should be avoided. In this setting, lidocaine has been used successfully, as have β -adrenergic antagonists.¹⁰⁵

Hyperbaric oxygen (HBO) was studied in a rat model of severe kerosene-induced pneumonitis.¹³⁴ HBO at 4 ATA showed some benefit in 24-hour survival rates. No follow-up studies have been performed. Patients with CCl₄ poisoning, however, may benefit from hyperbaric oxygen.^{27,158} ([Antidotes in Depth: A37](#)).

In the past, hospital admission was routinely recommended for patients who ingested hydrocarbons, because of concern over possible delayed symptom onset and progression of toxicity. Several reports documented patients with relatively asymptomatic presentations who rapidly decompensated with respiratory compromise. However, progressive symptoms after hydrocarbon ingestion are rare,^{8,94} and these recommendations predate noninvasive assessments of gas exchange. In a retrospective study of 950 patients, only 14 (1.5%) had progression of pulmonary toxicity.⁸ Of these 14, seven had persistence of symptoms for less than 24 hours. Eight hundred patients were asymptomatic on initial evaluation with normal chest radiographs, remained asymptomatic after 6 to 8 hours of observation, and had a normal repeat radiograph. No patient in this group of 800 had progressive symptoms, and all were discharged without clinical deterioration. Seventy-one of the 950 patients had initial respiratory symptoms but were asymptomatic at initial medical evaluation. Of the 71 patients, 36 had radiographic evidence of pneumonitis. Of these 36 patients, two (6%) developed progression of pulmonary symptoms during the 6-hour observation period. Of the 35 who had a normal radiograph, two (6%) developed pulmonary symptoms and radiographic pneumonitis during the 6-hour observation period. The four patients who were hospitalized for progression of symptoms became asymptomatic over the next 24 hours and had no complications.

A separate poison center–based study evaluated 120 asymptomatic patients over an 18-hour telephone follow-up period.⁹⁴ Sixty-two patients had initial pulmonary symptoms that quickly resolved. One of the 62 patients (1.6%) developed progressive pulmonary toxicity. This patient was hospitalized and had resolution of symptoms within 24 hours without complications.

A number of investigators have suggested protocols for determining which patients can be safely discharged.^{8,81,94} None of these protocols has been prospectively validated. However, rational guidelines for hospitalization can be recommended. Those patients who have clinical evidence of toxicity, and most individuals with intentional ingestions, should be hospitalized. Patients who do not have any initial symptoms, have normal chest radiographs obtained at least 6 hours after ingestion, and who do not develop symptoms during the 6-hour observation period can be safely discharged. Care should be individualized for patients who are asymptomatic but who have radiographic evidence of hydrocarbon pneumonitis and for patients who have initial respiratory symptoms but quickly become asymptomatic during medical evaluation. Reliable patients may be considered for possible discharge with next-day follow-up.

SUMMARY

- Hydrocarbons are a diverse group of xenobiotics that can cause toxicity by inhalation, ingestion, or dermal absorption.
- Populations at particular risk for toxicity include children who ingest hydrocarbon compounds, workers who are

occupationally exposed by inhalation or dermal absorption, and youths who intentionally inhale volatile hydrocarbons.

- Aspiration pneumonitis is the primary concern after hydrocarbon ingestion, with the risk of aspiration dependent on many factors including viscosity, volatility, surface tension, amount ingested, and the presence of emesis.
- Many hydrocarbons are poorly absorbed from the gastrointestinal tract and unlikely to produce systemic poisoning. Acute systemic toxicity is unlikely to occur in the absence of CNS effects such as excitation or sedation.
- An exposed child who is asymptomatic after 6 hours of observation and who has a normal chest radiograph taken after 6 hours of observation is most likely safe for discharge.

109 TOXIC ALCOHOLS

Sage W. Wiener

HISTORY AND EPIDEMIOLOGY

Methanol was a component of the embalming fluid used in ancient Egypt. Robert Boyle first isolated the molecule in 1661 by distilling boxwood, calling it spirit of box.²⁹ The molecular composition was determined in 1834 by Dumas and Peligot, who coined the term “methylene” from the Greek roots for “wood wine.”²⁰² Industrial production began in 1923, and today most methanol is used for the synthesis of other chemicals. Methanol containing consumer products that are commonly encountered include model airplane and model car fuel, windshield washer fluid, solid cooking fuel for camping and chafing dishes, photocopying fluid, colognes and perfumes, and gas line antifreeze (“dry gas”). Methanol is also used as a solvent by itself or as an adulterant in “denatured” alcohol.¹³⁸ Most reported cases of methanol poisoning in the United States involve ingestions of one of the above products, with more than 60% involving windshield washer fluid,⁵⁸ although most inhalational exposures involve carburetor cleaner.⁸⁷ In a Tunisian series, ingested cologne was the most common etiology.³⁰ In a Turkish series, cologne was also most common, accounting for almost 75% of ingestions.¹²⁹ Perfume was one of several exposures in a patient with methanol poisoning in a report from Spain,¹⁷³ and methanol poisoning from cologne has also been reported in India.¹² There are sporadic epidemics of mass methanol poisoning, most commonly involving tainted fermented beverages.^{23,130} These epidemics are a continuing problem in many parts of the world.^{16,146,153,166,187,218,257}

Ethylene glycol was first synthesized in 1859 by Charles-Adolphe Wurtz and first widely produced as an engine coolant during World War II, when its precursor ethylene oxide became readily available.⁷⁰ Today its primary use remains as an engine coolant (antifreeze) in car radiators. Antifreeze used in gas tanks generally contains methanol. Because of its sweet taste, it is often consumed unintentionally by animals and children. Aversive bittering agents may be added to ethylene glycol containing antifreeze to try to prevent ingestions by making the antifreeze unpalatable, an approach required by law in two states. However, there is no evidence that this strategy is effective, and comparisons in poison center data between ethylene glycol ingestions where bittering agents were required and where they were not have revealed no significant differences in frequency or volume of ingestion, or any other outcome variable (Chap. 135).^{253,254}

Isopropanol is primarily available as rubbing alcohol. Typical household preparations contain 70% isopropanol. It is also a solvent used in many household, cosmetic, and topical pharmaceutical products. Perhaps because it is so ubiquitous, inexpensive, and with a common name that contains the word “alcohol”, isopropanol ingestions are the most common toxic alcohol exposure reported to poison centers in the United States,³⁶ typically in cases where it was used as an ethanol substitute (Chap. 136).

CHEMISTRY

Alcohols are hydrocarbons that contain a hydroxyl (-OH) group. The term “toxic alcohol” traditionally refers to alcohols other than ethanol that are not intended for ingestion. In a sense, this is arbitrary, since all alcohols are toxic, causing inebriation and end organ effects if taken in excess. The most common clinically relevant toxic alcohols are methanol and

ethylene glycol (1,2-ethanediol). Ethylene glycol contains two hydroxyl groups; molecules with this characteristic are termed diols or glycols because of their sweet taste. Other common toxic alcohols include isopropanol (isopropyl alcohol or 2-propanol), benzyl alcohol (phenylmethanol), and propylene glycol (1,3-propanediol). Primary alcohols, such as methanol and ethanol, contain a hydroxyl group on the end of the molecule (the terminal carbon), whereas secondary alcohols, such as isopropanol, contain hydroxyl groups bound to middle carbons. Glycol ethers are glycols with a hydrocarbon chain bound to one or more of the hydroxyl groups (forming the basic structure $R^1O-CH_2-CH_2-O-R^2$ or $R^1O-CH_2-CH_2-CH_2-OR^2$). Glycol ethers commonly encountered include ethylene glycol butyl ether (also known as 2-butoxyethanol, ethylene glycol monobutyl ether, or butyl cellosolve), ethylene glycol methyl ether (2-methoxyethanol), and diethylene glycol (2,2'-dihydroxydiethyl ether). Poisoning with these compounds may clinically resemble toxic alcohol poisoning, and diethylene glycol is discussed in detail in Special Considerations: SC7.

TOXICOKINETICS/TOXICODYNAMICS

Alcohols are rapidly absorbed after ingestion^{74,88} but are not completely bioavailable because of metabolism by gastric alcohol dehydrogenase (ADH), as well as by first-pass hepatic metabolism. Occasionally, delayed or prolonged absorption may occur.⁶⁸ Although methanol may also be absorbed in significant amounts by inhalation, poisoning by this route is uncommon. In workers exposed to methanol fumes from industrial processes for up to 6 hours at concentrations of 200 ppm (Occupational Health and Safety Administration {OSHA} permissible exposure limit {PEL}), there was no significant accumulation of methanol or its metabolite formate.¹⁴⁸ Another study showed that with methanol use in the semiconductor industry, ambient methanol concentrations generally do not approach this OSHA limit even in a room with poor ventilation due and with no local exhaust ventilation.⁸⁰ Surprisingly, concentrations far in excess of the OSHA PEL can be present within the passenger compartment of a car when using the windshield wipers with methanol-containing windshield washing fluid.²¹ No cases of human poisoning are reported from this type of exposure, probably because these concentrations are not sustained over a long time. Two patients with occupational inhalational exposure aboard a tanker carrying methanol developed consequential toxicity, including the death of one; both patients reportedly used appropriate personal protective equipment.¹³⁹ Additionally, cases of inhalational poisoning are reported with intentional inhalation of methanol as a drug of abuse, typically in the form of carburetor cleaning fluid (“huffing”) (Chap. 84), and with massive exposures of rescue workers responding to the scene of an overturned rail car filled with methanol.^{14,75,87,158,244,250} Two case series suggest that patients who present after chronic inhalation of methanol have good clinical outcomes with folate and ADH blockade alone and without need for hemodialysis,^{20,158} although in another series, patients with inhalational exposure were as likely to require dialysis as patients with methanol ingestion.⁸⁷ Transdermal methanol exposure can be consequential if exposure is prolonged.¹³¹ Ethylene glycol has low volatility and is not reported to cause poisoning by inhalation. In one study, human volunteers inhaled vaporized ethylene glycol at a concentration of 1340 to 1610 ppm for 4 hours to simulate an industrial exposure. Afterward, the volunteers had detectable but not clinically significant concentrations of ethylene glycol and its metabolites.²⁴² Most alcohols have some dermal absorption, although isopropanol and methanol are able to penetrate the skin much better than ethylene glycol.^{63,154,248} Most reported cases of toxic alcohol poisoning by this route involve infants⁵⁷ because of their greater body surface area-to-volume ratio, and likely this also involved simultaneous inhalation. One reported case of transdermal methanol poisoning involved a 51 year-old woman, but details of the exposure were not reported.²³⁰ Another case involved a 52 year-old woman who reportedly frequently massaged with methanol containing cologne and spirit over the course of 3 days. That patient suffered significant visual and neurologic sequelae despite aggressive treatment with ethanol and hemodialysis.² One methanol fatality was deemed to be caused by transdermal absorption (in addition to blunt trauma) when high tissue methanol concentrations were measured in the absence of detectable methanol in the gastrointestinal tract,¹⁵ but inhalational exposure could also conceivably have contributed. When human volunteers were exposed to 100% ethylene glycol applied to a 66 cm² area of skin under an occlusive dressing for 6 hours, detectable but not clinically significant amounts were absorbed.²⁴²

Once absorbed, alcohols are rapidly distributed to total body water. In human volunteers given an oral dose of methanol on an empty stomach, the measured volume of distribution was 0.77 L/kg, with a distribution half-life of about 8 minutes.⁸⁸ This is only slightly longer than the absorption half-life, so serum concentrations typically peak soon after ingestion and then begin to fall.

Without intervention, toxic alcohols are metabolized through successive oxidation by ADH and aldehyde dehydrogenase (ALDH), each of which is coupled to the reduction of NAD^+ to NADH. Methanol is metabolized to formaldehyde, then to formic acid (Fig. 109–1). Ethylene glycol has two hydroxyl groups that are serially oxidized by ADH and ALDH, producing, in turn, glycoaldehyde, glycolic acid, glyoxylic acid, and finally oxalic acid (Fig. 109–2). Like ethanol, this metabolism follows zero-order kinetics, with a rate that is reported to be about 10 mg/dL/h.^{50,118,169} Additionally, this rate is apparently unchanged in chronic ethanol users.^{97,98} Alternate minor metabolic pathways such as catalase exist for methanol and ethylene glycol.

FIGURE 109–2. Pathways of ethylene glycol metabolism. Thiamine and pyridoxine enhance formation of nontoxic metabolites.

After methanol ingestion, the formate metabolite is bound by tetrahydrofolate and then undergoes metabolism by 10-formyltetrahydrofolate dehydrogenase to carbon dioxide and water. Ethylene glycol is also metabolized to ketoadipate and glycine using thiamine and pyridoxine as cofactors.¹⁷⁸ Because of the low toxicity of these ethylene glycol metabolites, these normally minor metabolic pathways are attractive targets for potential therapy.

Methanol and ethylene glycol are eliminated from the body as unchanged parent compounds. When kidney function is normal, ethylene glycol is cleared with a half-life of approximately 11 to 18 hours.^{28,47,226} Methanol does not have significant renal elimination (about 1% of the ingested dose in patients with intact hepatic metabolism) and is cleared much more slowly than is ethylene glycol, presumably as a vapor in expired air (half-life, 30–54 hours).^{34,144,188}

PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS

Acute Central Nervous System Effects

All alcohols may cause inebriation, depending on the dose. Based on limited animal data, it appears that higher molecular weight alcohols are more intoxicating than lower molecular weight alcohols on a molar basis (therefore, isopropanol \approx ethylene glycol $>$ ethanol $>$ methanol).²⁵¹ However, the absence of apparent inebriation does not exclude ingestion, particularly if the patient chronically drinks ethanol and is thereby tolerant to its central nervous system (CNS) effects.²³⁵ Additionally, serum methanol concentrations of 25 to 50 mg/dL may potentially be associated with toxicity, whereas in most states one may legally drive a car with a blood alcohol concentration of up to 80 mg/dL.

The CNS manifestations of toxic alcohol poisoning are incompletely understood. It is assumed by analogy that inebriation is similar to that of ethanol, where effects are mediated through increased γ -aminobutyric acid (GABA)–ergic tone both directly and through inhibition of presynaptic GABA, GABA_A receptors as well as inhibition of the N-methyl-D-aspartic acid glutamate receptors.^{10,42,90,105,172} Although the CNS effects of other alcohols are clinically similar, there is no direct evidence that they are mechanistically the same.

Metabolic Acidosis

Metabolic acidosis with an elevated anion gap is a hallmark of toxic alcohol poisoning. This is a consequence of the metabolism of the alcohols to toxic organic acids. The acids have no rapid natural metabolic pathway of elimination, and therefore they accumulate, unlike acetic acid resulting from ethanol metabolism, which can enter the Krebs cycle. In methanol poisoning, formic acid is responsible for the acidosis, whereas in ethylene glycol poisoning, glycolic acid is the primary acid responsible for the acidosis, with other metabolites making a minor contribution. An exception to the formation of an acid metabolite is isopropanol, which is metabolized to acetone. Acetone is a ketone, not an aldehyde, and therefore cannot be further metabolized by ALDH (Fig. 109–3). Thus isopropanol has no organic acid metabolite and does not cause metabolic acidosis. In fact, ketosis without acidosis is essentially diagnostic of isopropanol poisoning. Occasionally, a non-anion gap (hyperchloremic) metabolic acidosis may result from ethylene glycol poisoning (almost 18% in one series), often concurrently with anion gap acidosis.²²⁹ The mechanism for this is unclear, but a similar pattern has been observed in the setting of diabetic ketoacidosis, alcoholic ketoacidosis, and toluene poisoning.

FIGURE 109–3. Isopropanol metabolism.

End-Organ Manifestations

Additional end-organ effects depend on which alcohol is involved. Methanol causes visual impairment, ranging from blurry or hazy vision or defects in color vision, to “snowfield vision” or total blindness in severe poisoning. Although it is counterintuitive, vision loss may not be symmetric.^{48,161} On physical examination, central scotoma may be present on visual

field testing, and both hyperemia and pallor of the optic disc, papilledema, and an afferent papillary defect are described as characteristic findings.^{23,183,260} Electroretinography may demonstrate a diminished b-wave,²⁴⁰ a marker of bipolar cell dysfunction, and optical coherence tomography (similar in principle to ultrasound, but using reflected light waves to image translucent tissues) may demonstrate peripapillary nerve fiber swelling and intraretinal fluid accumulation.⁷⁷ Formate is a mitochondrial toxin, inhibiting cytochrome oxidase and it thereby interferes with oxidative phosphorylation.^{69,179,180} Although it is unclear why this results in ocular toxicity while other tissues are relatively spared, retinal pigmented epithelial cells and optic nerve cells appear to be uniquely susceptible.^{66,165,239,240} Proteomic analysis of retinas in rats poisoned by methanol showed 24 proteins were different from baseline (14 increased, 10 decreased),⁴⁶ so the underlying pathophysiology of retinal toxicity from methanol may be more complex than is currently understood. Years after exposure, optic nerve atrophy, disc pallor and severe cupping may be still be present, even with normal intraocular pressure.²²¹

Interestingly, neurons in the basal ganglia appear to be similarly susceptible to this toxicity. Bilateral basal ganglia lesions, bilateral necrosis of the putamen (with or without hemorrhage), and less commonly, caudate nucleus are characteristically abnormal visualized on cerebral computed tomography (CT) or magnetic resonance imaging (MRI) after methanol poisoning.^{3,6,12,24,26,60,64,72,78,99,100,123,124,131,190,205,208,217,224,237,243} While lesions of this type are nonspecific, and may also occur in hypoxia, hypotension, and carbon monoxide poisoning, in methanol poisoning they occur in the absence of hypotension and hypoxia,¹⁶⁷ suggesting a direct toxic mechanism. Patients have developed parkinsonism after poisoning by methanol, a finding consistent with the lesions in the basal ganglia lesions.^{92,166,200} In one series, typical radiological lesions were present in six of nine cases.²¹⁷ Other CNS lesions reported include necrosis of the corpus callosum¹³⁴ and intracranial hemorrhage.^{13,216} Pathologic examination of the brain reveals lesions similar to those found radiologically.¹³² Increased glial fibrillary acidic protein and decreased CD34 expression are pathologic markers in affected tissues, although how these relate to the underlying pathophysiology is not yet clear.²⁴¹

Both retinal and neurological toxicity of methanol poisoning may be permanent. Among 86 survivors of a methanol poisoning outbreak in Estonia in 2001, 26 had died six years later (many from alcohol intoxication) and 33 could not be tracked down. Of the five patients who could be found out of 20 patients that had been discharged with retinal or neurologic sequelae, all had persistent effects. Interestingly, 8 out of the 22 patients found who were discharged without sequelae had newly identified neurological and visual sequelae 6 years later (among 66 initially discharged without sequelae). The newly identified visual sequelae may have actually been present initially but missed due to lack of ophthalmologic evaluation, or symptoms may have developed more gradually in these patients. New neurologic symptoms were probably due to continued drinking.¹⁸⁶ In another series from Iran, 37 of 50 survivors of methanol poisoning with retinal toxicity were followed 1 year later; 16 patients improved before discharge from the hospital. Seven patients had their visual disturbance resolve within 2 weeks; 5 were blind at discharge but partially recovered within 3 to 4 weeks; 5 were blind at discharge and had no improvement 1 year later; and 4 were blind at discharge, had partial recovery within 1 month, but then had worsening vision within the subsequent 9 months.²¹¹ This suggests that, long-term outcomes of retinal toxicity are difficult to predict.

Rarely, injury to other tissues may also occur. Both acute kidney injury (AKI) and pancreatitis are reported after methanol poisoning.^{102,140} For unclear reasons, one case series showed a much higher incidence of pancreatitis (50%)¹⁰² and in another, 11 of 15 patients had pancreatitis,²⁴⁷ but this is not typical. Some of the AKI that results from methanol poisoning may be due to myoglobinuria.⁹¹ In one series of methanol poisoned patients with AKI about half had associated myoglobinuria, presumably due to atraumatic rhabdomyolysis. One reported patient with methanol poisoning had rhabdomyolysis severe enough to cause compartment syndrome in both legs, requiring fasciotomy.⁵¹ Patients with AKI were also more likely than a control group of patients to have severe poisoning, as manifested by low initial serum pH, high initial osmolality, and high peak formate concentration.²⁴⁷ Pathologic abnormalities of the liver, esophagus, and gastric mucosa are also found in some fatal cases of methanol poisoning.^{4,44}

The most prominent end-organ effect of ethylene glycol is nephrotoxicity. The oxalic acid metabolite forms a complex with calcium to precipitate as calcium oxalate monohydrate crystals in the renal tubules, leading to AKI.^{73,93,95,168,196,234,238} The diagnosis of ethylene glycol poisoning has been established at autopsy by demonstrating this abnormality, including in one homicide case^{11,151}; in another case, the diagnosis was established by kidney biopsy.¹³⁴ Although the intermediate products of ethylene glycol metabolism, and possibly ethylene glycol itself, are directly toxic to the renal tubules in some studies,^{49,73,195,198} this appears not to occur at clinically relevant concentrations.⁹³ Currently no explanation exists for the presence of necrotic lesions to the glomerular basement membrane on some pathology specimens⁷³ as oxalic acid generally does not cause glomerular injury.¹²⁵

Ethylene glycol can occasionally affect other organ systems. In severe poisoning, the oxalic acid metabolite may be present in sufficient amounts to cause hypocalcemia following precipitation as calcium oxalate. This can result in prolongation of the QT interval on the electrocardiogram and ventricular dysrhythmias.²¹⁵ Cerebral edema was present on CT scan in two patients who died of ethylene glycol poisoning.^{76,238} Two reported patients had delayed neurological

manifestations. One patient developed increased intracranial pressure, with papilledema and an abducens (CN VI) palsy approximately 9 days after recovering from acute ethylene glycol poisoning and without another clear etiology.⁵⁹ Another patient developed the same cluster of delayed effects (increased intracranial pressure, papilledema and an abducens palsy) on day 13 of hospitalization, after fomepizole, thiamine, pyridoxine, and hemodialysis. He subsequently developed a facial (CN VII) palsy, sensory neuropathy, and autonomic neuropathy, including postural hypotension and gastroparesis.¹⁹⁹ Precipitation of calcium oxalate crystals in the brain was found on autopsy after severe ethylene glycol poisoning^{8,73,76} and may account for the multiple cranial nerve abnormalities that occasionally develop,^{59,231} although there is as yet no direct evidence of causation. Peripheral polyradiculoneuropathy can be diagnosed by electromyography and nerve conduction studies in cases of ethylene glycol poisoning,^{7,17} and intracranial hemorrhage involving the globus pallidus can occur.³⁹ A leukemoid reaction may also occur in the setting of severe ethylene glycol poisoning, but the mechanism remains unclear.^{160,176} One pediatric case of hemophagocytic syndrome and liver failure in the setting of ethylene glycol poisoning resulted in fatality.¹⁴⁵ Parkinsonism can also occur.²⁰⁰ Two severe cases of unintentional ethylene glycol ingestion in the United Kingdom resulted in blindness and deafness; one with associated cranial neuropathies and one with multiple peripheral neuropathies.^{41,62} One patient had a myocardial infarction with ST segment elevation while poisoned with ethylene glycol, but survived after cardiac catheterization and placement of five stents, as well as treatment with ethanol and hemodialysis.²³⁶ Finally, death can result from massive ethylene glycol ingestion with no elevation of its metabolites, suggesting direct toxicity of the alcohol, probably through respiratory depression.⁸¹

Hemorrhagic gastritis is associated with isopropyl alcohol intoxication. Although this is often assumed to be caused by a local irritant effect, one reported case of hemorrhagic gastritis after percutaneous isopropanol exposure suggests that this is not the only mechanism, and may in fact be a specific end-organ effect.⁶⁵ Hemorrhagic tracheobronchitis has occurred in fatal cases of isopropanol aspiration.⁵ The acetone metabolite of isopropyl alcohol may also interfere with some creatinine assays, causing a falsely elevated result,¹³⁷ but it does not actually cause AKI.

DIAGNOSTIC TESTING

Toxic Alcohol and Metabolite Concentrations

Serum methanol, formate, ethylene glycol, oxalate, and isopropanol concentrations (as appropriate) would be the ideal tests to perform when toxic alcohol poisoning is suspected shortly after exposure. However, these concentrations are most commonly measured by gas chromatography with or without mass spectrometry confirmation, methodologies that are not available in most hospital laboratories on a 24 hour basis, if at all. In fact, in many hospitals these are only available as “send out” tests, so results arrive too late for early clinical decision making.¹³³ Enzymatic assays for methanol, formic acid, ethylene glycol, and glycolic acid have been developed,^{27,232,249} and these may lead to more readily available clinical tests. However, the commercial product is currently approved for veterinary use only. This veterinary test is effective for confirming the qualitative presence of ethylene glycol in human poisoning, although false positives may occur with propylene glycol.¹⁵⁷ In a murine model, a commercially available ethanol in saliva point of care test can detect the presence of a low concentration of methanol but not ethylene glycol.⁹⁶ Unfortunately, it would not distinguish between methanol and ethanol, limiting the clinical utility of this test. A group in Finland described a point of care breath test for methanol, using a portable Fourier transform infrared (FT-IR) analyzer similar to the “breathalyzers” used by law enforcement agents.¹⁴⁷ Although analyzers like this are used to check for methanol as a combustion product in industry, they are not yet approved for medical use in the United States. Once approved, they would be useful for early clinical decision making because they are easy to use and provide a rapid result. They also can provide continuous monitoring of concentrations, a feature that would be very helpful during hemodialysis. Unfortunately, this methodology could not be used to detect ethylene glycol because of its low volatility.

Patients presenting late after ingestion may already have metabolized all parent compound to toxic metabolites and thus may have low or no measurable toxic alcohol concentrations. Fortunately, the enzymatic assay for ethylene glycol is also capable of detecting glycolic acid, although as mentioned, this assay is approved only for veterinary use. Some authors have actually advocated for routine testing for glycolic acid in addition to testing for the parent compound when ethylene glycol poisoning is suspected.¹⁹⁸ Serum and urine oxalate concentrations may also be determined,²³³ although their clinical utility is unclear. Similarly, a formate concentration may be valuable when a patient presents late after methanol ingestion.^{115,184} Formate was detected in blood samples from 97% of patients who died of methanol poisoning in one series; all of these patients also had detectable blood or vitreous methanol concentrations.¹²⁶ Clearly, a low or undetectable toxic alcohol concentration must be interpreted within the context of the history and other clinical data, such as the presence of acidosis and end-organ toxicity, with glycolate and formate concentrations as potentially valuable additions.

Samples must be handled correctly for accurate toxic alcohol results. Particularly with the more volatile alcohols methanol and isopropanol, concentrations may be falsely low if the sample tubes are not airtight. This commonly results in low concentrations if alcohol concentrations are done as “add on” tests to samples already opened for electrolyte or osmol

determinations.

Other alcohols such as benzyl alcohol and propylene glycol are not routinely assessed for by gas chromatography. Thus these xenobiotics present a much greater diagnostic challenge than methanol and ethylene glycol. Enzymatic assays for methanol or ethylene glycol would also fail to detect these, although false positive ethylene glycol tests may occur if propylene glycol is present. Thus a high index of suspicion is critical to establishing the diagnosis in these cases. If suspected on the basis of history, specific toxic alcohol testing should be performed.

Once alcohol concentrations are obtained, their interpretation represents a further point of controversy. Traditionally, a methanol or ethylene glycol concentration greater than 25 mg/dL has been considered toxic, but the evidence supporting this as a threshold is often questioned. In a case series of methanol poisoned patients from the 1950s, a methanol concentration of 52 mg/dL was the lowest associated with vision loss.²³ This may have been the origin of the 25 mg/dL threshold, incorporating a 50% reduction as a margin of safety. However, the patient with the 52 mg/dL concentration presented 24 hours after his initial ingestion, and therefore was much more severely poisoned than suggested by his serum concentration at that point. In fact, almost all reported cases of methanol poisoning involve patients with delayed presentations who already have a metabolic acidosis.¹⁴¹ The only reported patient who went untreated after presenting early with an elevated methanol concentration (45.6 mg/dL) never developed acidosis or end-organ toxicity.^{32,141} A systematic review found that 126 mg/dL was the lowest methanol concentration resulting in an acidosis in a patient who arrived early after ingestion and met the inclusion criteria. The authors concluded that the available data are currently insufficient to apply a 25 mg/dL treatment threshold in a patient presenting early after ingestion without acidosis.¹⁴¹ However, until better data are available demonstrating the safe application of a higher concentration, it seems prudent to use a conservative concentration such as 25 mg/dL as a threshold for treatment.

Because of the problems with obtaining and interpreting actual serum concentrations, many surrogate markers have been used to assess the patient with suspected toxic alcohol poisoning. The initial laboratory evaluation should include serum electrolytes, including calcium, blood urea nitrogen, serum creatinine concentrations, urinalysis, measured serum osmolality, and a serum ethanol concentration. Blood gas analysis with a lactate concentration is also helpful in the initial evaluation of ill appearing patients.

Anion Gap and Osmol Gap

For a full discussion of the anion gap concept, refer to [Chap. 19](#). As previously discussed, anion gap elevation is a hallmark of toxic alcohol poisoning. In fact, the possibility of methanol or ethylene glycol poisoning is often first considered when patients present with an anion gap acidosis of unknown etiology, frequently with no history of ingestion. Unless clinical information suggests otherwise, it is important to exclude metabolic acidosis with elevated lactate concentration and ketoacidosis, which are the most common causes of anion gap acidosis, before pursuing toxic alcohols in these patients. This is because of the extensive evaluation required and expensive, potentially invasive course of therapy to which they are otherwise committed. However, elevated lactate concentrations may be present in the setting of both methanol and ethylene glycol poisoning.^{163,170,219}

The unmeasured anions in toxic alcohol poisoning are the dissociated organic acid metabolites discussed above. The acidosis takes time to develop, sometimes up to 16 to 24 hours for methanol. Thus the absence of an anion gap elevation early after reported toxic alcohol ingestion does not exclude the diagnosis. If ethanol is present in the body, the development of acidosis will not begin to occur until enough ethanol has been metabolized that it can no longer effectively inhibit ADH (see Ethanol Concentration, below).

A potential early surrogate marker of toxic alcohol poisoning is an elevated osmol gap (the principles and the calculations are discussed in detail in [Chap. 19](#)). However, it is important to recognize that osmol gap elevation is neither sensitive nor specific for toxic alcohol poisoning. Since a baseline osmol gap is generally not available when evaluating a patient (with rare exceptions),¹¹³ and a normal osmol gap ranges from -14 to +10 osmols, so-called “normal” osmol gaps cannot exclude toxic alcohol poisoning.¹⁰⁸ For example, in a patient with a baseline osmol gap of -10, a current gap of +5 potentially represents a methanol concentration of 47 mg/dL or an ethylene glycol concentration of 93 mg/dL, values that might require hemodialysis. Inversely, a moderately elevated osmol gap (+10 to +20) is not necessarily diagnostic of toxic alcohol poisoning because other disorders such as alcoholic ketoacidosis and metabolic acidosis with elevated lactate concentration, may raise the osmol gap.²¹⁴ Furthermore, mean osmol gaps vary within populations over time, further limiting their utility.¹⁴² However, a markedly elevated osmol gap (>50) is difficult to explain by anything other than a toxic alcohol.

Further complicating matters, the anion gap and osmol gap have a reciprocal relationship over time. This is because soon after ingestion, the alcohols present in the serum raise the osmol gap but do not affect the anion gap because metabolism to the organic acid anion has not yet occurred. As the alcohols are metabolized to organic acid anions, the anion gap rises while the osmol gap falls, because the metabolites are negatively charged particles that have already been accounted for in the calculated osmolality by doubling of the sodium. Thus patients who present early after ingestion may have a high osmol gap and normal anion gap, while those who present later may have the reverse.^{111,117} [Figure 109–4](#)

depicts a more intuitive visual representation of this process.

FIGURE 109-4. The reciprocal relationship of anion gap and osmol gap over time (hours). Note that patients presenting early may have a normal anion gap while patients who present late may have a normal osmol gap.

One retrospective and one prospective study have attempted to evaluate the performance characteristic of the osmol gap as a diagnostic test. Although in both cases, the osmol gap performed fairly well, the studies were small, 20 patients with toxic alcohol poisoning in the retrospective study and 28 patients with methanol poisoning in the prospective study, and the prospective study identified three patients with significant poisoning and acidosis but “normal” osmol gaps, defined in the study as less than 25.^{111,162} Therefore, these data do not eliminate the concern that a patient with significant poisoning could be missed by relying on the osmol gap alone to exclude poisoning.

Ethanol Concentration

A serum ethanol concentration is an important part of the assessment of the patient with suspected toxic alcohol poisoning. As discussed in [Chap. 19](#), the ethanol concentration is necessary to determine the calculated osmolality. In addition, because ethanol is the preferred substrate of ADH (4:1 over methanol and 8:1 over ethylene glycol), a significant concentration would be protective if coingested with a toxic alcohol. In fact, ethanol concentrations near 100 mg/dL virtually preclude toxic alcohols as the cause of an unknown anion gap metabolic acidosis because the presence of such a concentration should have prevented metabolism to the organic acid. A possible exception would be ingestion of ethanol several hours after ingestion of a toxic alcohol.¹⁰⁶ If a breath alcohol analyzer is used to determine ethanol concentration, a false positive ethanol value may be obtained if significant methanol concentrations are present, and the machine may not indicate that an interfering substance is present (as it does with acetone).⁴⁰ Therefore, even if a prehospital breath alcohol analyzer indicates a significant ethanol concentration, this should be confirmed by determining the serum ethanol concentration.

Lactate Concentration

Both methanol and ethylene glycol poisoning can result in elevated lactate concentrations, for different reasons. Formate, as an inhibitor of oxidative phosphorylation, can lead to anaerobic metabolism and resultant lactate elevation. Additionally, metabolism of all alcohols results in an increased NADH/NAD⁺ ratio, which favors the conversion of pyruvate to lactate. Furthermore, hypotension and organ failure in severely poisoned patients can also produce an elevated lactate concentrations. However, lactate production by these mechanisms tends to result in serum concentrations no greater than 5 mmol/L.

In ethylene glycol poisoning, the glycolate metabolite may also cause a false positive lactate elevation when measured by some analyzers, particularly with whole blood arterial blood gas analyzers. The Radiometer ABL series (625, 700, 725, 825, 835) is most widely reported to result in a false positive lactate; other specific models implicated to varying degrees include: Beckman LX 20, Bayer/Chiron Rapidlab series (860, 865), Roche Modular, Architect c8000, Vitros Fusion 5.1, Cobas Integra, GEM Premier 4000 and Hitachi 911 analyzers, but not the Vitros 950 or Vitros 250 or the Beckman Coulter DxC-800 chemistry analyzer.^{35,45,53,71,163,170,175,191,197,213,256} In such cases, the degree of lactate elevation directly correlates

with the concentration of glycolate present,^{163,170} and the artifact results from the lack of specificity of the lactate oxidase enzyme used in these machines,^{170,175,197,256} although direct oxidation of glycolate at the analyzer anode is also suggested as a possible mechanism.²²² Thus the presence of a “lactate gap” might also be used to diagnose ethylene glycol poisoning in hospitals where lactate assays are available with and without sensitivity to glycolate, or two lactate assays with different sensitivities to lactate.^{222,246} Ingestion of propylene glycol can also result in elevated lactate concentrations, but in this case, it is not a false positive lactate but rather an accurate measurement of a metabolite of propylene glycol.^{127,128}

Other Diagnostics

Serum glucose concentration is generally obtained as part of routine laboratory analysis. Hyperglycemia, defined as serum glucose greater than 140 mg/dL (7.77 mmol/L) in nondiabetic patients, portended a greater risk of death after methanol poisoning, with an odds ratio of 6.5 in one retrospective study.²¹⁰ This has not yet been prospectively validated.

The urine may provide information in the assessment of the patient with suspected ethylene glycol poisoning. Calcium oxalate monohydrate (spindle-shaped) and dihydrate (envelope-shaped) crystals may be seen when the urine sediment is examined by microscopy, although this finding is neither sensitive nor specific.^{79,118,174} In fact, calcium oxalate crystals were present in the urine of only 63% (12 of 19) of patients with proven ethylene glycol ingestion in one series.³³

Some brands of antifreeze contain fluorescein to facilitate the detection of radiator leaks. If one of these products is ingested and the urine is examined with a Woods lamp within the first 6 hours, there may be urinary fluorescence.²⁵⁵ Gastric aspirate may also demonstrate fluorescence.⁵⁶ False positive fluorescence may result from examining the urine in glass or plastic containers due to the inherent fluorescence of these materials, so if this test is performed, an aliquot of the urine should be poured onto a piece of white gauze or paper. Recent work has suggested a lack of utility of this test. Almost all children had urinary fluorescence, and there was poor interrater agreement in determining fluorescence of specimens.^{43,189}

The evaluation of patients with known or suspected ethylene glycol poisoning should also include serum calcium and creatinine concentrations. Patients with methanol poisoning and abdominal pain also warrant an assessment of liver function tests and serum lipase because of the possibility of associated hepatitis and pancreatitis.

Although characteristic brain CT and MRI abnormalities are frequently reported in the setting of methanol poisoning, it is unclear what role they have in the routine evaluation of these patients. The presence of putaminal hemorrhage or insular subcortex white matter necrosis was associated with a greater odds ratio of death (8 and 10, respectively) in one study of patients with methanol poisoning.²³⁷ However, in the absence of neurological abnormalities on physical examination, routine CT or MRI are probably not indicated.

Diagnostic Testing and Risk Assessment

Increases in both anion gap and osmolar gap may be useful for risk stratification in methanol poisoning, and a venous or arterial blood gas should be performed. A review of reported toxic alcohol cases attempted to identify risk factors for mortality in adults with methanol or ethylene glycol poisoning. For methanol poisoning, no patient with an anion gap less than 30 mEq/L or an osmolar gap less than 49 osmols died. A pH less than 7.22 was an even better predictor of mortality, as no patient with a pH greater than 7.22 died. For ethylene glycol, the tests were less useful. One patient with an osmolar gap of only 25 osmols died, no patient with an anion gap less than 20 mEq/L died, and pH did not predict mortality with statistical significance.⁵⁴ This study has been criticized for missing a substantial number of patients,²⁰⁷ and it still needs to be validated in another population. Another retrospective study of risk factors for poor outcomes in methanol poisoning only found that pH less than 7.00 (as well as coma or a >24-hour delay to presentation) was associated with death.¹⁰³ In a large series from several epidemics of methanol poisoning, a pH less than 7.00 and coma were again identified as risk factors associated with death. In patients with a pH less than 7.00, PCO₂ greater than or equal to 23.3 mm Hg (3.1 kPa) was also a risk factor.¹⁸⁵ In methanol poisoned patients unlikely to die, the pH may still be useful for predicting retinal toxicity. Another retrospective study examined markers for poor visual outcome after methanol poisoning and again found pH to be the best predictor, with a pH greater than 7.20 associated with a high likelihood of only transient visual sequelae.⁶¹

MANAGEMENT

As always, immediate resuscitation of critically ill patients starts with management of the airway, breathing, and circulation. Because alcohols may cause respiratory depression and coma, intubation and mechanical ventilation are commonly necessary for patients with severe poisoning. Alcohol-induced vasodilation combined with vomiting often lead to hypotension, and many patients will require fluid resuscitation with intravenous crystalloid. Gastrointestinal decontamination is rarely, if ever, indicated for toxic alcohols because of their rapid absorption and limited binding to activated charcoal. However, placement of a nasogastric tube and aspiration of any gastric contents is probably worthwhile

in intubated patients, as absorption may sometimes be delayed after a large dose.⁶⁸

Alcohol Dehydrogenase Inhibition

The most important part of the initial management of patients with known or suspected toxic alcohol poisoning (after initial resuscitation) is blockade of ADH. This allows for the establishment of a definitive diagnosis and arrangement for hemodialysis while preventing the formation of toxic metabolites. Additionally, in some cases ADH blockade may itself serve as definitive therapy.

Teleologically, ADH exists for the purpose of metabolizing ethanol, so it is not surprising that the enzyme has a higher affinity for ethanol than for other alcohols. ADH metabolizes ethanol with a K_m that is 15 to 20 times lower in vitro than its K_m for methanol metabolism and 67 times lower than its K_m for ethylene glycol metabolism.^{55,192,193} Thus significant concentrations of ethanol prevent metabolism of other alcohols to their toxic products. Ethanol is the traditional method of ADH inhibition and may still be the only option in some institutions. A 10% solution is administered through a central venous catheter and titrated to maintain a serum concentration of 100 mg/dL (Antidotes in Depth: A31). Complications of the infusion include hypotension, respiratory depression (with supratherapeutic concentrations), flushing, hypoglycemia, hyponatremia, pancreatitis, and gastritis, as well as inebriation, so patients receiving intravenous ethanol require admission to an intensive care unit. The true incidence of these adverse events is unclear. In one study, complications of ethanol infusion in children were uncommon.²⁰³ However, in another review of 49 adults treated with ethanol infusions for toxic alcohol poisoning, 92% of patients had at least one adverse event.²⁵² Orally administered ethanol is also effective and may be considered when intensive monitoring is unavailable, particularly in rural areas where there may be a significant delay in getting the patient to a hospital.

Fomepizole is a competitive antagonist of ADH that has many advantages over ethanol. It reliably inhibits ADH when administered as an intravenous bolus every 12 hours, and concentrations do not need to be monitored as with an ethanol infusion.^{33,34} It does not cause inebriation and is associated with fewer adverse effects, so it does not require intensive care unit monitoring.^{18,19,33,34,150} For these reasons, it has become the preferred method of ADH blockade, despite being significantly more expensive than ethanol.²²⁵ In theory, the savings in intensive care unit (ICU) monitoring and laboratory costs probably compensate for the higher drug cost of fomepizole, unless the patient requires intensive monitoring regardless based on the severity of illness.²⁸ However, one study showed that even after fomepizole was introduced to their hospital, 95% of patients received ICU admission and hemodialysis,⁸⁹ so this may not be a large area of savings. Additionally, the cost difference will vary depending on the setting of poisoning and the health care delivery system of the country involved. A series in Belgium found that treating with ethanol and dialysis was much less expensive than fomepizole without dialysis within their system.⁹

The dose of fomepizole is 15 mg/kg intravenously as an initial loading dose followed by 10 mg/kg every 12 hours. Bradycardia and hypotension may occur after fomepizole infusion, so vital signs should be monitored closely during and after each dose.¹⁴⁹ After 48 hours of therapy, fomepizole induces its own metabolism, so the dose must be increased to 15 mg/kg every 12 hours. Although one review advocates giving doses as high as 20 mg/kg every 12 hours with no adjustment for induced metabolism,²⁵ this dosing regimen is not supported by the manufacturer or any current clinical guideline. A review of reported cases in which fomepizole was used in children suggests that it is safe and effective with the same weight based dosing as adults.³² Pharmacokinetic data from a human volunteer study show that there is no significant difference in serum concentrations between oral and intravenous fomepizole.¹⁶⁴ However, there is currently no oral preparation of fomepizole on the market (Antidotes in Depth: A30).

Indications for fomepizole or ethanol therapy may be based on the history or on laboratory data. Any patient with a believable history of methanol or ethylene glycol ingestion should be treated until concentrations are available because, as previously discussed, early symptoms and laboratory markers other than serum concentrations may be absent. In addition, any patient with an anion gap acidosis without another explanation or a markedly elevated osmol gap should also be treated. Once concentrations are available, therapy should be continued until the serum toxic alcohol concentration is predicted or measured to be below 25 mg/dL, although as discussed previously, this value is based more on consensus opinion than on data.

The antiretroviral medication abacavir is a substrate for ADH and seemed to delay metabolism of methanol in one case.⁸⁴ It has been suggested that abacavir could have potential as an alternative to fomepizole in places where fomepizole is unavailable.²¹² Similarly, ranitidine is an inhibitor of gastric and hepatic ADH, and in a rat model, ranitidine improved pH, formate concentrations, and retinal histopathology.⁶⁷ Although these are intriguing possibilities, there are currently no data to support the use of either abacavir or ranitidine in human poisoning.

Hemodialysis

The definitive therapy for symptomatic patients poisoned by toxic alcohols is hemodialysis. Hemodialysis clears both the alcohols and their toxic metabolites from the blood and corrects the acid–base disorder. The indications for hemodialysis

have become more restricted with the advent of fomepizole because of its effectiveness combined with its low incidence of adverse effects. Particularly for ethylene glycol, which can generally be expected to be cleared within a few days once ADH is blocked as long as the glomerular filtration rate is normal,^{37,152,245} some have argued that the risks of an invasive and costly procedure such as hemodialysis are not warranted in minimally symptomatic patients with normal kidney function and without acidosis.^{38,82} Even a patient with a moderately elevated serum methanol concentration, 80 mg/dL (2.5 mmol/L), was successfully treated with fomepizole alone.²⁰⁴ Based on toxicokinetic data, some patients with methanol poisoning might be treated without dialysis or with delayed dialysis, particularly in epidemic scenarios, where the need for hemodialysis may exceed the availability.¹¹² However, patients with end-organ toxicity or severe acidosis have significant amounts of toxic metabolites, a problem not addressed by ADH blockade, and acidosis is associated with poor prognosis.¹⁵⁶ Additionally, although formate is normally cleared rapidly once ADH is blocked, the half-life increases with higher serum methanol concentrations and varies from 2.5 to 12.5 hours.^{101,110} In one patient with severe poisoning, formate was eliminated at an extremely slow rate with a half-life of 77 hours until hemodialysis was initiated,¹¹⁴ underscoring the importance of hemodialysis in patients with significant metabolic acidosis. In addition, patients with AKI will not eliminate the parent compound once ADH is blocked, except very slowly in expired air in the case of methanol. Therefore, the consensus is that metabolic acidosis, signs of end-organ toxicity, including coma and seizures, and AKI are indications for hemodialysis. A “toxic concentration” and possibly a very high osmol gap¹⁹⁴ are more relative indications for hemodialysis, and decisions must be based on the judgment of the clinician for the specific clinical scenario, considering the available resources. Some authors have advocated using toxic metabolite concentrations if available as additional criteria for hemodialysis. In data from one case series, an elevated formate concentration appears to be a better predictor of clinically important toxicity than methanol concentrations.¹⁸⁴ Similarly, glycolate concentrations are a better predictor of death and AKI than ethylene glycol concentrations.¹⁹⁸ However, although clearance of formate by hemodialysis is substantial,^{121,122,136} the overall clearance in one case series did not appear to increase significantly above endogenous clearance in patients also treated with folate and bicarbonate.¹³⁶ Some have questioned the data quality in this series, pointing out that (a) the predialysis clearance in two patients was calculated using only two data points and in the three others was calculated using three points, generally considered the minimum; (b) several patients actually had decreased clearance during dialysis, contradicting all previous data; and (c) two of the patients had variable blood flow during dialysis.^{112,258}

The American Academy of Clinical Toxicology (AACT) practice guidelines are ambiguous with respect to a threshold methanol concentration for hemodialysis in the absence of acidosis, AKI, end-organ effects, or worsening clinical status.¹⁸ However, until additional investigations are completed, a methanol concentration of 50 mg/dL remains a reasonable indication for consideration of hemodialysis in the absence of significant acidosis or end-organ effects. The AACT guidelines for ethylene glycol actually advise against hemodialysis for a concentration alone without any of these clinical indications.¹⁹ Still, ethylene glycol remains the second most common toxin to be removed by hemodialysis in the US.¹⁰⁹ Clearly, there are still insufficient data to establish threshold concentrations of alcohols or their metabolites where dialysis is absolutely indicated, and the decision is ultimately a subjective one based on the overall clinical scenario.¹⁰⁷

Although hemodialysis effectively clears isopropanol and acetone from the blood, it is rarely if ever indicated for this purpose. Because isopropanol does not cause a metabolic acidosis and very rarely results in significant end-organ effects, the risks of hemodialysis likely outweigh the benefits.

Many patients will require multiple courses of hemodialysis to clear the toxic alcohol. Nephrologists may estimate the dialysis time required using the formula:

$$t = -V \ln(5/A)/0.06k$$

where t is the dialysis time required to reach a 5 mmol/L toxin concentration, V is the Watson estimate of total body water (liters), A is the initial toxin concentration (mmol/L), and k is 80% of the manufacturer specified dialyzer urea clearance (mL/min) at the observed initial blood flow rate.^{104,259} Additionally, the normalization of the osmol gap may guide the required duration of dialysis, but this has not been validated.¹¹⁶ Regardless of how the duration of dialysis is determined, ADH blockade should be continued during and after hemodialysis until a subsequent concentration of the offending alcohol is confirmed to be nontoxic. Ethanol infusion rates must be increased during hemodialysis to maintain a therapeutic serum concentration as the ethanol is cleared (Antidotes in Depth: A31). Fomepizole should be redosed every 4 hours during hemodialysis to maintain therapeutic serum concentrations.^{18,19}

Continuous renal replacement therapy (CRRT) such as venovenous hemodiafiltration has occasionally been used in patients with toxic alcohol poisoning. Hemodialysis is much more efficient at clearing xenobiotics than CRRT and is virtually always the preferred modality if available. However, if there is a contraindication to hemodialysis, such as hemodynamic instability or severe cerebral edema,⁸⁶ or if hemodialysis is unavailable, CRRT may be considered as an intervention that may offer some advantage over no extracorporeal removal at all. In a pharmacokinetic model, the addition of CRRT can decrease the treatment time by 40%.⁵⁵

Adjunctive Therapy

There are several therapeutic adjuncts to ADH blockade with or (especially) without hemodialysis that should be considered for these patients. One of the differences that has been invoked to explain the absence of retinal toxicity from methanol in some species is the relative abundance of hepatic folate stores in these species such as the rat. Folate and leucovorin enhance the clearance of formate in animal models.^{181,182} Thiamine enhances the metabolism of ethylene glycol to ketoacid, and pyridoxine enhances its metabolism to glycine and ultimately hippuric acid (Fig. 109–2).¹⁷⁸ While all of these modalities offer theoretical advantages, they have yet to be proven to change outcome in humans. However, there is one human case report showing enhanced formate elimination with folinic acid therapy.¹²⁰ Additionally, some have suggested that the apparent lack of an increase in formate clearance by hemodialysis was because it was dwarfed by the effectiveness of folate supplementation in both the study group and the control group.¹³⁶ Because of the safety of vitamin supplementation, the potential benefit likely outweighs the risk of therapy (Antidotes in Depth: A10, A14, and A24).

Formate is much less toxic than undissociated formic acid, likely because formic acid has a much higher affinity for cytochrome oxidase in the mitochondria, the ultimate target site for toxicity.¹⁵⁵ In addition, the undissociated form is better able to diffuse into target tissues.¹²² Alkalinization with a bicarbonate infusion shifts the equilibrium to favor the less toxic, dissociated form, in accordance with the Henderson-Hasselbalch equation. This also enhances formate clearance in the urine by ion trapping.¹²² Data from uncontrolled case series demonstrate that patients treated with bicarbonate alone had better than expected outcomes after severe methanol poisoning,¹⁷⁷ but the results are equivocal in patients also treated with ADH blockade and hemodialysis.^{34,119,171} Additionally, the severity of the metabolic acidosis after methanol poisoning is a good predictor of severe neurological effects such as coma and seizures,¹⁵⁶ although it is not proven that alkalinization prevents these effects. However, in the absence of contraindications to a bicarbonate infusion (eg, hypokalemia, volume overload), alkalinization should be used in the patient with suspected methanol poisoning and a significant acidemia. A blood pH greater than 7.20 is a reasonable endpoint. Alkalinization should also be considered for patients with ethylene glycol poisoning and life-threatening metabolic acidosis.

Aluminum citrate has potential promise as an adjunctive therapy for ethylene glycol poisoning. It interacts with the surface of calcium oxalate monohydrate crystals and prevents their aggregation. This decreases tissue damage from calcium oxalate monohydrate crystals in an in vitro model of human proximal tubule cells.⁹⁴ However, there are not yet any in vivo human studies or even case reports, so it cannot be recommended for clinical use.

Some have suggested a possible benefit of corticosteroids for retinal injury following methanol poisoning. In an uncontrolled case series, 13 of 15 patients showed improvement in their vision after treatment with 1 g of methylprednisolone daily for 3 days, with one having worsening vision and one unchanged.²²³ A patient in another case report had permanent vision loss despite corticosteroid therapy using the same regimen.⁷⁷ Another uncontrolled case series used a slightly different dosing regimen, with 250 mg of intravenous methylprednisolone administered every 6 hours followed by oral prednisolone 1 mg/kg daily for 10 days. After treatment, the mean best corrected visual acuity improved, but methanol concentrations were not reported so exposure was not confirmed, and acuity data were not reported for individual patients, so it is unclear whether any worsened.^{1,209} Another series of four patients with mild methanol poisoning given the same treatment regimen showed some improvement in vision.²²⁸ An uncontrolled case series with delayed presentations, incomplete follow up, and an inconsistent corticosteroid regimen showed improvement in some patients.^{206,220} In a series of 63 patients with methanol poisoning from a 2009 epidemic in India, all patients with evidence of optic neuritis (at least 60% of 46 survivors), were treated with retrobulbar injections of triamcinolone (dose not reported); 75% had some improvement.²¹⁸ Currently, however, these data are insufficient to support the routine use of corticosteroids in methanol poisoning.²²⁷

SPECIAL POPULATIONS

Pregnant Women and Perinatal Exposure

There are very few reported cases of pregnant women with toxic alcohol poisoning, but some conclusions can be drawn from the available data. Toxic alcohols readily cross the placenta, and perinatal maternal methanol ingestion has resulted in death of a newborn.²² One woman was initially misdiagnosed with eclampsia after ingesting ethylene glycol and presenting with seizures and metabolic acidosis in her 26th week of pregnancy. An emergency cesarean section was performed, and she was later treated with hemodialysis and ethanol once the correct diagnosis was recognized. The child was severely ill, with an initial pH of 6.63 and an initial serum ethylene glycol concentration of 220 mg/dL. The baby was treated with exchange transfusion and ultimately survived without sequelae after a long hospital course.¹⁴³ In rat but not rabbit models of chronic high dose ethylene glycol exposure, fetal axial skeletal malformations occur and are thought to be caused by glycolate.⁵² No human case of chronic exposure has yet been reported.

OTHER ALCOHOLS

Propylene Glycol

Propylene glycol is commonly used as an alternative to ethylene glycol in “environmentally safe” antifreeze. It is also used as a diluent for many pharmaceuticals (such as phenytoin and lorazepam). This alcohol is successively metabolized by ADH and ALDH to lactate, so a metabolic acidosis results. This can result in extremely high lactate concentrations typically that would be incompatible with life if generated by any disease process. In other diseases associated with lactate accumulation and acidosis, the lactate is a reflection of underlying anaerobic metabolism, a marker of severe illness rather than part of the underlying pathophysiology. Lactic acidosis from propylene glycol is surprisingly well tolerated because it represents nothing more sinister than its own metabolism, and it is rapidly cleared by oxidation to pyruvate, which then undergoes normal carbohydrate metabolism ([Chap. 55](#)).

Benzyl Alcohol

Benzyl alcohol is used as a preservative for intravenous solutions. Although it is no longer used in neonatal medicine, it has been responsible for “neonatal gasping syndrome,” involving multiorgan system dysfunction, metabolic acidosis, and death because of its metabolism to benzoic acid and hippuric acid ([Chap. 55](#)).^{83,159}

SUMMARY

- Early symptoms of toxic alcohol poisoning may include inebriation, and subsequent toxicity results from metabolism to organic acid anions that cause metabolic acidosis and end organ effects.
- The time required for this metabolism results in a delay before toxicity is clinically manifest.
- Until serum concentrations are available, the serum anion gap and osmol gap may help with decision making but do not exclude toxicity if the history is concerning.
- Therapy consists of ADH antagonism with fomepizole or ethanol, as well as adjunctive therapy with bicarbonate, folate or folinic acid, pyridoxine, and thiamine.
- Hemodialysis is the definitive therapy for clinically ill patients as it removes the alcohol as well as toxic metabolites while correcting the metabolic acidosis and electrolyte abnormalities.
